TWO BEE BOOKS

A Collection of Papers on Bee-keeping in India. Published under the Orders of the Government of India, in the Revenue and Agricultural Department, 1883. (Calcutta: Office of the Superintendent of Government Printing, India, 1883.)

The Honey-Bee: its Nature, Homes, and Products. By W. H. Harris, B.A., B.Sc. With Eighty-two Illustrations. (London: The Religious Tract Society, 1884.)

THE thin folio issued by the Indian Government is very redolent of red-tape, since it contains not only a large number of reports from forest and district officers, and other persons in various parts of India, but also the whole of the official correspondence, memoranda, and indorsements connected with the same. Moreover, it is almost a misnomer to call it a collection of papers on "Bee-keeping," since at least nine-tenths of the reports state that domesticated bees are quite unknown in their districts; and the bulk of the matter (nearly a hundred pages of close print) is occupied with accounts of native methods of taking the combs of wild bees and preparing the wax, and with very imperfect descriptions of the various kinds of honey-producing bees in each district. The general result of the inquiry, as stated in a "Resolution" of the Revenue and Agricultural Department, is the following:—

"The industry is unlikely ever to be one of great importance in India. It can only be followed in the hills, where flowers abound throughout the greater part of the year, or in forests, where food is equally plentiful. In the populous country of the plains, bee-keeping as a general industry seems impracticable. Under these circumstances there is little or no call for action on the part of the Government."

Notwithstanding this somewhat depressing outcome of a laborious inquiry, some interesting details may be found in the storehouse of facts here brought together. At the commencement of the Report attention is drawn to Moorcroft's account of bee-keeping in Cashmere:—

"Their domestication there is so general that in some parts of the country a provision is made for hiving them in every house as it is being built. Spaces are left empty in the walls about 14 inches in diameter, and 2 feet, the average thickness of the walls, in length, which are carefully lined with a mixture of mortar, clay, and chopped straw, and closed at the inner end with a flat tile. There are ten or a dozen of these hives built into the walls of every house. The bees are hived exactly as in Europe, but the comb is gathered differently and in a way well worth following at home. It is done by the father of the house removing the flat tile, and at the same time blowing the smoke of a smouldering wisp of straw he holds in the other hand vigorously through the hive, on which the bees at once leave the hive, and he gathers in their store of honey. He then replaces the flat tile at the inner end of the hive, and the bees, after recovering their stupefaction, gradually return to it. The same colony of bees thus produce honey year after year in the same hive, and generation after generation, and have probably done so from the original Aryan settlement of the Cashmere Valley. In consequence of their being thus literally domiciliated with the human race, the bees of Cashmere are milder in their manners than those of any other country, although they have a most villainous sting when unduly provoked to use it. Their honey is as pure, and clear, and sweet, Moorcroft says, as the finest honey of Narbonne."

In a statement on bee-culture in Cashmere by a zemindar, it is said that hives are now very numerous, as they have been on the increase for several years, and the method of keeping them is very similar to that described by Moorcroft. But Mr. R. Morgan, Deputy Conservator of Forests, Madras, protests against the recommendation of smoking out the bees, as barbarous. It is, however, no doubt well suited to native wants, as hives are not required to be indefinitely increased, and there is no sale for swarms.

A very simple mode of bee-keeping is described as practised by the people of Mysore:—

"In March or April they besmear the concave part of an old earthen pot with honey-wax, make holes in the pot, take it to the jungles, and place it upside-down on a piece of wood or a slab of stone. The bees are attracted to the pot by the smell of the wax, and, when the person intending to domesticate them finds, after a trial of four or six days, that they have taken to remain in the pot, he goes to the jungle on a dark night, removes the pot after

having covered it with a blanket, and places it either on a tree near or under the eaves of his house, or in any adjoining place. Each man keeps pots varying in number from one to four. He need not do anything beyond keeping the pots as aforesaid. They store honey between April 15 and June 15; and between the latter date and the end of July the keeper gathers it in, leaving a small portion to serve as food for the bees."

Mr. R. Morgan, Deputy Conservator of Forests, Madras, gives an interesting account of the honey-bees of the Wynaad. He says that the best honey-producing flower of Southern India is the Strobilanthes, of which there are numerous species, which almost all flower once in seven years, dying down entirely, and afterwards a fresh growth springing up from seed. The Strobilanthes is a shrubby genus of Acanthaceæ, mostly with blue or purple flowers, and the statement about their flowering only once in seven years is probably a popular delusion, like that of the Aloe flowering once in a century. The bees build their combs on the ledges of inaccessible precipices, often overhanging rivers, or on lofty horizontal limbs of the largest forest trees, and the combs are usually $3\frac{1}{2}$ to 4 feet in length and 2 feet in diameter. The natives take the honey on dark nights by means of long cane or bamboo ladders, either erected against the tree or rock or suspended from above, and they carry torches, and knives to cut away the combs. The bees are roused by the glare of the torches, but do not sting, although in the daytime they are terribly pugnacious, and many a sportsman and traveller has barely escaped with his life after disturbing them. Mr. Morgan states that he can give numerous instances of men, cattle, horses, and even fowls and pigeons being killed by these bees.

The Deputy Conservator of Forests, East Salween, describes some remarkably large combs, one of which was 7 feet long and 6 feet deep in the widest part. The bees are fond of particular trees, and he states that on one Kanyin tree (*Dipterocarpus alatus*) he counted no less than thirty-nine combs, some of prodigious size. The trees are here ascended by means of pegs driven in the trunk, as in Borneo, and the bees are partially stupefied by a smoke torch.

These are samples of the better kind of reports that have been obtained from hundreds of districts in India. There is a monotonous similarity in large numbers of them, and it may be doubted whether the information afforded is worth the labour and cost it has entailed.

Mr. Harris's little volume on "The Honey-Bee" affords a striking contrast to the preceding work, both in its elegant get-up and excellent illustrations, its wide range of matter, and the clearness and condensation of its style. It treats in a pleasant and well-informed manner not only of bee-keeping but of the bees themselves and all that relates to them. We have a chapter on the literature of bees, from the Egyptian monuments and the Vedas to Shakespeare, Huber, and modern writers. Each subject is treated in a separate short chapter, so that we have chapters on "The Queen Bee," "The Workers," "Wax," "Bee-bread," &c., and even one on "Mead," including its use in ancient times and Queen Elizabeth's receipt for its manufacture. Hives, the Enemies, and the Diseases of Bees are all separately treated, as well as their "Intellect and Instinct," their "Relation to Flowers," and the "Superstitions connected with Bees."

From so condensed a work it is difficult to find passages suitable for extract, but the following illustration of the powers of intellect manifested by bees may be taken as a fair specimen of the author's style:—

"Again, let us revert to the manufacture of queens by the workers. If at the time of the removal or loss of the mother-bee in any way, there should be unhatched princesses in the hive, no attempt will be made to follow the course adopted in the absence of such royal progeny. In the *latter* case—that is, when there is no royal brood—there must be a distinct conception, first, of their bereavement; secondly, of the hopelessness of a sovereign appearing in the ordinary way. Then a judgment is formed of the proceedings necessary for making a queen, and action immediately follows. Not only so, but as if to secure themselves against the repetition of their calamity, they prepare not *one* queen, but *several*, so that, if the first which comes to maturity be lost, there may be others in reserve. A further act of definite judgment appears in this; for if one only were produced and lost, they would be powerless to repeat the process, as all the rest of the worker brood would, in the meantime, have advanced far beyond the stage at which its transformation would be possible. The bees then, with admirable prevision, forbear to risk all the future of their community on one hope of a queen."

In adducing the construction of the cells as a proof of pure instinct of the highest order, Mr. Harris is hardly on secure ground, since he omits to notice the researches of Mr. Darwin proving that the method of cell-building is very simple, and consists, fundamentally, in forming circular cells the size of which is determined by that of the bee's body, and gnawing away all the superfluous wax in the angles till the hexagonal form is produced. He is also hardly justified in the statement that "all these and other circumstances connected with the construction of their dwellings attest the possession of an innate faculty *needing no instruction from the elders of the hive*." The last statement (which we have italicised) is surely unprovable, and as every young bee necessarily begins work in the midst of her elders, and has done so during the countless generations of the past, it seems more probable that a considerable portion, though not perhaps the whole, of the bees' wonderful constructive power, is due to direct imitation and instruction.

On the whole, we can recommend this little book as a very comprehensive summary of what is known about bees and bee-keeping, at once attractive to the young who wish to learn something about these marvellous little creatures, and at the same time containing all the information necessary for the beginner in apiculture. The illustrations are both well chosen and beautifully executed, and the work is altogether so daintily got up as to render it especially suited for a gift to intelligent boys and girls.

A. R. W.

DR. KLEIN ON MICRO-ORGANISMS

Micro-Organisms and Disease. By E. Klein, M.D., F.R.S. (London: Macmillan and Co., 1884.)

THERE can be no doubt of the value and excellence of this little book. Dr. Klein is one of the very few men in this country who are continually working and experimenting with Bacteria and similar forms. His

instructions and advice as to methods of study are invaluable, and his opinions on the numerous debatable questions connected with micro-organisms entitled to the highest respect. Dr. Klein has descended, as it were, from his position of experimentalist and observer, in order to place before the scientific public in a compact form a *résumé* of what is known at this moment concerning disease-producing micro-organisms. He classifies these organisms as Micrococci, Bacteria, Bacilli, Vibriones, Spirobacteria, Yeast-fungi, and Mould-fungi, and gives *seriatim* under each head, accompanied by numerous figures, often original, an account of such forms as have been found in association with disease. He refers the reader to the original writings in which this or that organism has been described, and whilst he sometimes judiciously throws doubt on a claim to pathogenic powers, he is entirely relieved from the responsibility of a critic in all cases by the disclaimer in his preface and by the fact that he obviously intends to leave the question in most cases to further inquiry. As an illustrated catalogue of reputed pathogenic Schizophytes, with references to original authorities, the work is invaluable.

At the same time Dr. Klein does, as so ripe a student of these questions must, commit himself to very definite opinions on some of the great problems of what it is convenient to term "Bacteriology." Dr. Klein clings to the belief that speaking broadly the forms known as Micrococci, Bacteria, Bacilli, Vibriones, and Spirilla breed true and are to be recognised as true genera. This opinion is traceable to the fact that his studies have been chiefly (like those of Koch, who holds a similar view) carried out on parasitic (*i.e.* pathogenic) Schizophytes. And it is highly probable that it is more difficult (in some cases impossible) to break down the specific form by change of environment of a parasitic Schizophyte than of free-living kinds. But Dr. Klein has himself shown (p. 109) that Bacillus (*B. anthracis*) when cultivated in a certain way becomes Micrococcus (torula-form), and other similar instances are to be found in his book. Had he dealt with free-living Schizophytes as well as parasitic ones, he would have found ample evidence of the transformation, in the course of growth and division, of Micrococci into Bacteria, of these into Bacilli, and of these into Vibriones and Spirilla, and of each of these directly or indirectly into the other forms. The instability of the forms presented by particular kinds of Bacteria does not however imply, as has been assumed by some writers (Billroth *e.g.*), that there is only one "species" of Schizophyte. Such use of terms would lead to the statement that there is only one "species" of organism in all creation. The instability of the forms of Schizophytes merely implies that the range of presently observable specific characters taken as a whole (which forms the true limits of what mankind at the moment calls a "species") is *not* simply and directly coincident with the range of one particular and readily observed set of characters, namely, those of form. A great deal more depends upon the question of transmutability of the forms of Schizophytes than is admitted, at present, by pathologists. We would merely warn them that the doctrine of fixity of the forms of pathogenic Schizophytes is as much an *assumption* and as much to be received with caution as is the contrary doctrine of the universal transmutability of such forms. One great fact is certain, viz. that *some* Schizophytes do exhibit the *positive* evidence of change of form in the course of growth under varying conditions.

Dr. Klein has a most interesting chapter on the conversion of innocuous into pathogenic organisms and *vice versâ*, in which he criticises with great ability the results of Buchner and Nägeli on the one hand, and of Pasteur on the other. Valuable as such critical dissertations are, Dr. Klein will agree with us in thinking his experiments of greater value. We should be sorry were the test-experiments which they suggest to be delayed in consequence of the apparently satisfactory character of the reasonings which he and others have very properly adduced. The fact is that the proportion of what we know by careful experiment and observation in reference to Bacteria and their allies—as compared with what we must soon know and can see how to know if only time and ability are directed to the research—is so small that conclusions and generalisations are not useful except as suggestions to those who are in the thick of the work. More experiment, more trial of every conceivable condition of growth and nutrition, applied to every kind of Schizophyte observed and yet to be discovered, is imperatively called for.

Who can say that much is known as yet about these organisms, when even so earnest a student of them as Dr. Robert Koch did not know that his so-called "cholera comma-Bacillus" occurs in the mouths of nearly every healthy man, woman, and child?

Dr. Klein has rendered a generous service to future students of Bacteria by the publication of this little book. The woodcuts are very abundant, and sufficient to give an idea of the forms as they appear when stained by coloured reagents. The botanical and chemical aspects of the Schizophytes are necessarily not dealt with in this treatise.

E. RAY LANKESTER

OUR BOOK SHELF

A New Method of treating Glaucoma, based on recent researches into its Pathology. By Geo. Lindsay Johnson, M.A., M.B., B.C. Cantab. (H. K. Lewis, 1884.)

THIS little *brochure* is written by a Cambridge graduate who has devoted considerable time and attention to the study of diseases of the eye, and who has devised a new and very serviceable form of ophthalmoscope. The proposition he endeavours to establish is "that the ordinary method of treatment for glaucoma by iridectomy, though highly successful in acute forms of the disease, is nevertheless both uncertain and unsatisfactory in the chronic condition of glaucoma." The truth of this proposition all those who have had large experience in the performance of operations on the eye will freely admit: the reason is less easy to give. Dr. Johnson describes the lymphatic system of the eye, and adduces evidence to show that the aqueous humour is secreted by the ciliary processes and posterior surface of the iris, whilst it is drained off by the canal of Fontana, and the meshwork at the corneo-iridal angle. Any circumstance obliterating this angle is apt to induce glaucoma. It is certainly not due to swellings of the lens, since Brailey has shown that the lens is smaller in the glaucomatous than in the normal eye, but Dr. Johnson thinks that acute glaucoma may be referred to swelling and inflammation of the ciliary processes, whilst in chronic glaucoma there are slow and gradual changes in the ciliary body and in the lesions around the angle of the anterior chamber, which in his opinion explains the

different effects of iridectomy in cases of acute and chronic glaucoma. Dr. Johnson then proceeds to describe an operation which he terms scleral paracentesis, and describes as new, but which we have seen performed both by Mr. Hancock and by Mr. Power many years ago. In point of fact, Mr. Hancock's operation was a scleral paracentesis, and his view, which is not altogether incorrect, and was based on observation, was that in glaucoma a circumcorneal depression could be seen which he imagined to be due to the ciliary muscle, and his section, made with the same instrument recommended by Dr. Johnson, namely, a Wenzel's double-edged knife, was made through the sclera with the object of dividing the ciliary muscle; and the excellent results obtained in some cases show clearly that the escape of the vitreous which followed the incision, accompanied, when the anterior chamber was opened, by the aqueous humour, was quite enough to afford relief to all the symptoms and to restore vision, even if the spasm of the ciliary muscle was quite imaginary. We do not, however, wish to deprive Dr. Johnson of the credit of having thought out this method of procedure, though he may rest assured that he will meet with many cases of chronic glaucoma that will derive no benefit from scleral paracentesis, and that he will have to be careful in promising success from his operation in such cases.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

An Unnoticed Factor in Evolution

Two observed biological facts seem to oppose great difficulties to any explanation on evolution principles; difficulties admitted by evolutionists as well as their opponents. I mean—

(1) The fact that varieties produced by artificial selection, however divergent, are always fertile among themselves, while species supposed to have been produced naturally by an analogous process are often not mutually fertile even when very slightly divergent; and

(2) The fact that species evidently derived from a common ancestor, and differing only in small points of marking, though not fertile with one another, are often found side by side in places where it would seem that cross-breeding must prevent any division of the ancestral species into divergent branches.

The first seems to require that a period much greater than that of artificial selection should be necessary to produce sterility between descendants from the same ancestor; a supposition which would require an almost incredible period for evolution as a whole. The second seems to require that many species now intermixed should once have been geographically separated, sometimes in cases where this is very difficult to imagine. Both these difficulties are completely removed if we suppose mutual sterility to be not the *result* but the *cause* of divergence.

As far as can be judged, "sports" are as likely to occur in the generative elements (ova and spermatozoa) as in other parts of the body, and from their similarity in widely unlike groups it seems certain that a very slight variation in these elements would render their owner infertile with the rest of its species. Such a variation occurring in a small group (say the offspring of one pair) would render them as completely separate from the rest of their species as they would be on an island, and divergence (as Wallace has sufficiently shown) would begin. This divergence might progress to a great or a small extent, or even be imperceptible, but in any case the new species would be infertile with the species it sprang from.

If this theory be admitted, we must distinguish between varieties and species by saying that the former arise by spontaneous variations in various parts of the body, and only gradually become mutually infertile (thus becoming species), while the latter arise sometimes in this way, but sometimes by spontaneous variations in the generative elements, and are in this case originally mutually infertile, but only gradually become otherwise divergent.

I would suggest the following tests, and should be glad of any facts, from experience or from books, which can help in applying them:—

(1) If this theory is true we ought to find species (incipient) mutually infertile, but not otherwise distinguishable; and

(2) We ought to find that island and other isolated species which have arisen not by limited fertility but by geographical instead of physiological separation are often mutually fertile even when as widely divergent as the artificial varieties of dogs or pigeons.

EDMUND CATCHPOOL

The Grove, Totley, Sheffield, October 23

Earthquake Measurement

IN an article on "Earthquakes" in last week's NATURE (p. 608), Dr. H. J. Johnston-Lavis takes exception to the records of earthquake motion which I have published, on the ground of their complexity, and pronounces the Plain of Yedo unsuitable for earthquake observations.

Now this seems to me to be a very eclectic way of treating earthquakes. We can measure earthquakes only where we find them, and I suppose the first qualification in a site for an earthquake observatory is that there should be plenty of earthquakes. The Plain of Yedo possesses this qualification in a very high degree; and if the disturbances which occur in it are of a very much more complex character than our *a priori* notions about earthquakes may have led us to expect, it is not the Plain of Yedo that is to blame.

I fully agree that on a rocky formation the results will be different from those I found on an alluvial plain, but the instruments and methods which have been successful on the one are just as applicable to the other. The seismometers which have been used in Japan will serve to measure, with equal accuracy, earthquakes of a similar degree of destructiveness in other places, whatever be the nature of the ground. And several of the types already employed need little more than a change of scale in their construction to suit them for such formidable convulsions as the Ischian earthquake, to which your correspondent refers.

In describing and figuring a number of proposed seismographs, Dr. Johnston-Lavis has very frankly disclaimed a technical knowledge of mechanical construction, and for that reason all minute criticism of his suggestions may be withheld. If however he will refer to the *Transactions* of the Seismological Society of Japan, or to my "Memoir on Earthquake Measurement," he will see that some of the devices he suggests are not new. The plan of registering the amplitude of a pendulum's motion relatively to the earth by making the bob draw up a thread through a hole in a plate fixed below it was used some years ago by Dr. G. Wagener; and a massive slab free to roll on spherical balls formed in 1876 the seismometer of Dr. G. F. Verbeck. It was reinvented a year or two ago by Mr. C. A. Stevenson, and described by him before the Royal Scottish Society of Arts. The theory of the apparatus is discussed in §§ 31-32 of my memoir. Dr. Johnston-Lavis's plan of recording the azimuth of a movement by means of numerous electric contacts and "a pile of electromagnets" is a very retrograde step from the perfectly successful method, used in Japan, of resolving all horizontal movements into components along two fixed directions, these components being independently recorded in conjunction with the time.

Speaking of the use of the common pendulum as a seismometer, the author says that by using a short pendulum we may measure oscillations of short period, and by using a long pendulum we may measure slow earth-tiltings. Almost the reverse of this is the case. A short pendulum acquires, by earth movements of short period, a swing which cannot be distinguished from the movements we wish to measure, and whose extent depends on the accidental agreement of its period with theirs; but a short pendulum can be properly used to record slow earth-tiltings, with respect to which it is sensibly deadbeat. A long pendulum can be used to measure short-period movements; it can also be used (and its only advantage over a short pendulum is greater sensitiveness) to measure slow tiltings.

For vertical motion Dr. Johnston-Lavis condemns (but without giving any reason) my own and another vertical-motion seismograph—which theory and experience agree in proving

trustworthy—and proposes an instrument in which a weight drives a clock-train furnished with a centrifugal speed-indicator. The changes of apparent weight of the driver caused by the earth's up-and-down motion are to cause fluctuations in the speed of the driven train, which are to be recorded in conjunction with the time. The plan is, I think, new, but a less direct method of measuring vertical movement could scarcely be imagined. The fluctuations in speed will follow the changes of pull exerted by the driver with diminished amplitude and retarded phase, and superposed on them there will be fluctuations following no rule, due to inconstant friction and to mechanical imperfection of the train, as well as the continuous acceleration which follows the starting of the mechanism. To interpret the records would be altogether impracticable.

The design of a seismograph is a problem in applied dynamics which has of late years received a number of very satisfactory solutions. Of instruments capable of determining earthquake movements in absolute measure, and with reasonable exactness, there is now no lack; and it would be a pity if their wider employment were in any way retarded by the publication, on the authority of Dr. Johnston-Lavis, of suggestions which may fairly be said to lie outside the sphere of practical seismology.

University College, Dundee, October 27 J. A. EWING

The Sky-Glows

THE description of the sky-glows as seen by Prof. A. S. Herschel may justify an account of some seen near the University of Virginia, Virginia, during the past spring, from notes made at that time.

February 25.—For several days before this date there were (if one may so call them) the normal glows at and after sunset. On this day there was seen a single pink ray with well-defined edges, about 4° broad, perpendicular to the western horizon, reaching half way to the zenith.

March 24.—Ten minutes before sunset, the sun being behind a small cloud, the bright oval "glare" in the west, which preceded nearly all the after-glows, was seen with its centre at an elevation of 15° (all these heights are rough estimates). It was 10° in diameter, and was surrounded by a band of a hazy reddish ashen colour (this band was usually seen with the "glare") about 5° wide, which deepened in tint towards the horizon, and there spread out on each side of the "glare" so as to form a somewhat triangular support for it. At 6.30 the sun set. No colour had yet appeared on the eastern horizon. The "glare" now seemed almost triangular in shape, with the deepest ashen tints at the lower corners. As the sun descended, the "glare" diminished in intensity from the apex of the triangle. At 6.35 there was a ruddy colour on the eastern horizon, which spread in a triangular shape, apex upward, to a height of 25° to 30°, and at 6.40 was an exact image of the "glare" in the west, except that there were clear red tints instead of ashen, which were deepest at the lower corners of the triangle. The colour triangle then gradually rose from the eastern horizon, apparently following the sun, till at 6.48 the pink tint appeared in the western sky, increased in intensity, and was deepest at an elevation of 60°. The colour in the east was now gone. (Several attempts were made to observe the passage of colour across the zenith, but in no case was there success.) The western horizon was dazzling topaz-yellow, above the yellow pale blue, then faint pink to the deepest pink. The pink gradually descended toward the horizon, and when within 20° merged into the ordinary sunset colour at 7.0. The general phases of the glow were as follows:—Triangular ashen haze with oval "glare" in west, base of triangle on the horizon at sunset. Ten minutes later, triangular ruddiness in east, with base on the horizon. Another ten minutes, pink in the west. Ten minutes more, colour disappears. This succession was also noticed on March 15. On March 4 the glow in the west reached its most intense colour twenty minutes after sunset, but lasted twenty minutes, disappearing forty minutes after sunset.

On this evening (March 24) at 6.45, a cloud in the western sky, there being then no pink there, at an elevation of 35°, was coloured pale pea-green. This colour of the clouds floating at an elevation of 35° was seen on other days, while the clouds above and below retained their ordinary appearance.

March 26.—After the same phenomena as detailed in the last, even to the colour of the clouds, twenty minutes after the disappearance of the first glows, at 7.20 there was a pale rose-glow at an elevation from the western horizon of 30° to 35°, which reached almost to the Pleiades, of which six were then visible. This second glow lasted about twenty minutes, and seemed to descend to the horizon. It was almost identical with the first, but fainter.

March 29.—Same as preceding, without second after-glow; tints extended 60° to 70° from horizon.

These after-glows were noticed more or less during April, July, and September, and here in Cambridge during this month there have been several vivid displays. W. G. BROWN

Harvard College, Cambridge, Mass.,

I BEG to inclose you an extract from a letter lately received by me from my cousin, Mr. Leeming, in the hope that it may interest some of your readers. ELLEN A. DAY

Greycoat Hospital, Westminster, October 24

Extract from a Letter written by Thomas Leeming, Surgeon and Naturalist on Board H.M.S. "Gulnare," on the Admiralty Survey off Newfoundland

"*Galtois, Hermitage Bay, Newfoundland, September* 12, 1884

"There is one thing I have more than once forgotten to mention to you, that is, an unusual appearance in the sky there has been now for some months, which I think must be connected with the red sunsets of last winter. In the finest weather the sun has always about it a haze (not watery) extending some 20° or 30°, white in the day-time, but as the sun nears the horizon the sky has a pale salmon or ochrey tint. In the immediate neighbourhood of the sun, the sky is of a vivid whiteness. This appearance continues some time after sunset. I have tried more than once to reproduce this effect, with water-colours, but without success. Let me know if you have observed or heard of anything of the same kind. I may also mention that there has been until lately a great scarcity of stars; even on the fairest and darkest nights very few visible under the third magnitude, and the Milky Way scarcely to be seen at all. Things, however, are mending in this respect."

Peculiar Ice Forms

WALKING up from Chamounix to the Montanvert a fortnight ago, I came upon a form of ice which I think can hardly be of common occurrence, as I have not met with any description of it, and have only once before seen it, and then also on the same mountain side, and under similar conditions of season and weather.

The bank, which in this particular spot slopes at an angle of about 45°, and faces the north, is bare of vegetation for some 30 feet in depth, and 100 to 120 feet in length, the hillside above being clothed with moss, ferns, and the usual undergrowth. This bare slope was almost covered with a coating of ice nearly four inches in depth, and of very curious structure, being formed in four layers, the three upper layers each about an inch in depth, and the lowest, which rested on the soil, being from five-eighths to three-quarters of an inch. Each layer was composed of an aggregation of filaments or elongated crystals, one-sixteenth of an inch and downwards in diameter, and all of a length equal to the thickness of the layer, ranged side by side like organ-pipes or basaltic columns, and with pyramidal ends; the bottom points of one layer resting on the top points of the one below, so that the layers could be easily detached one from the other. The whole mass was pierced by vertical cylindrical cavities from half to a quarter of an inch or less in diameter, and in most cases penetrating from top to bottom, so that a pencil-case could be dropped through endways. A horizontal section presented somewhat the appearance of Gruyère cheese, minus the colour of course, and with the solid part showing the crystalline form described above.

The mass had evidently been pushed up from below, because, while the ice itself was perfectly white and colourless, it was covered at the surface by a layer of dirt which might very likely have concealed it from observation if it had not happened to be broken. There was a good deal of snow higher up—nine inches at the Montanvert—and the weather was fine, with bright sunny days and hard frost at night. This particular part of the bank was in shade all day, and hardly thawed at all. I imagine that the porous detritus forming the surface of the bank was underlain by hard rock (though it did not occur to me at the time to ascertain if it was so, and at what depth), and that the water

resulting from the melting by the sun of the snow above had percolated down to the hard substratum, along which it had run till it reached the place where the bare earth above it no longer protected it from radiation, and it then cooled and crystallised in this curious way, pushing itself up by expansion in so doing, each layer being the work of one night's frost. If this is correct, it is not difficult to understand what I assume to be the comparative rarity of this form of ice, since it would be seldom that all the necessary conditions would co-exist.

May I add, as the result of seven seasons' experience, that no one who has not tried it knows the charm of Switzerland in October. It is too late, of course, for high ascents, and the flowers are nearly gone; but an ordinary visitor, so long as he avoids the mists and clouds of the lowlands, by keeping at an elevation of three thousand feet and upwards, will find that the brightness and crispness of the air, the *enjoyableness* of the sunshine (which in August can at best be *tolerated*), the purity of the fresh snow, giving grandeur and beauty to lower heights which in summer are mere barren rocks, and the glory of the autumn colouring, not to mention the freedom from the plagues of heat, flies, and tourists, render October in Switzerland the most enjoyable month of the year. Hampstead, October 31

The Blackness of Tropical Man

A DECISIVE paper on the subject would have to be prepared elsewhere, but Hindostan presents an excellent field for amassing information with regard to the effects of an extraordinarily powerful sun on the human frame's exterior. In a very interesting article in NATURE for August 21 last (p. 401), "Why Tropical Man is Black," the cause is set down to the nerves of the skin being one and all highly sensitive to light, the optic nerves being merely some of those of the epidermis highly specialised by long-inherited modification, and the necessity for placing over them a pigment which will absorb light. Otherwise the intense nerve vibrations from a light of double degree power would soon degrade the tissues of the individual and exhaust his vitality.

It would have been all the better if a little more had been said about the way in which a patch of dark pigment cells round the transparent skin of the nerve endings, to be exalted into a special sense, heighten the rates of vibration; or how the selected tissue, at the same time securing the transmission of heat, as the constant accumulation of heat waves behind it, throws the molecular constituents of the protoplasm "into the highest rates of vibration possibly obtainable with the means at disposal."

Before turning to the experience India affords, it has to be noticed that, taking the centre of Europe as the standard of whiteness, it is not only going south that the population becomes successively blacker, but that there is a dark-skinned tendency in the races lying in the other direction, towards the Polar regions. Besides this, exposure in the bright days of August on the moors in the British Isles has the effect of browning the white skin exposed to light, and making it on the face and hands for a short time only a shade lighter than the lightest Indians. This can only be by the solar rays producing pigment in the skin.

On the contrary, the experience of Europeans in India is that the sun there does not burn; if anything, it rather whitens them and pales the complexion. It is only on certain occasions, when the sun is obscured by rain-clouds, it is cool, and the diffused light is of a particular but unascertained actinic quality, that the skin of a European is sunburnt. One may ride all day in the hottest sun and have no trace of sunburning.

Also were light the sole cause of a protection for the skin being required, this would be supplied by the clothing Europeans invariably have, except on hands and face; and they would be placed in about the same favourable position as the natives, if not more so, as those of the latter of the class of labourers prefer working almost entirely without clothes.

What is dreaded by Europeans all over India, and extending into Afghanistan, is the "Indian sun," when it is elevated more than ten or fifteen degrees above the horizon; and it is chiefly the head which it affects, and which has to be protected by non-conducting materials, forming the strange head-gear of the tropics. The playing of the sun on the rest of the body is disagreeable, but not dangerous.

Light and heat are one and the same, so that the nerves of sight are only a select number of those with which the skin is full, higher strung; but it is noticeable that, though heat is felt by any nerves of the skin indiscriminately, they are insensible to minute differences of heat, or in the periods of the heat-rays, so that no sense, so to speak, is conveyed by them. That is—though, as we know, all objects reflect as many heat-rays of different kinds as they do visual rays—we are not conscious of their form by a reception and discrimination of the varying periods of the heat-rays; we do not consciously see by heat.

The effect the Indian sun has on European health, sunstroke being said to be the work of a few minutes, shows that the nerves of the skin are sensitive to some rays besides those of light. In fact, the sun's rays of Hindostan must contain rays not found in the sunlight of most other parts of the world, which moreover penetrate the European's white skin tissues and clothing, while the natives can let it beat upon their bared heads with complete impunity.

There has never been a sufficiently minute comparison made between the pure solar diffraction spectrum, from the lowest lines to the highest, of India and that in other countries, such as Great Britain, America, the West Indies, and Australia. In many respects the West India Islands are as tropical as the East Indies, but those who have resided in the former and coming to the latter declare there is some quality they feel in the Indian sun that is absent in the West Indies; they can wear a simple straw hat in the one place, but could not attempt it anywhere throughout India. If the spectra were juxtaposed, it would no doubt be found that groups of rays in some portion of it, whether at the red or the violet end, were present to a much larger extent in the light of the Indian sun than either in Australia or the West Indies. It is of the greatest importance, in order to clear up this question, as well as to science in general, that those who have the means and time should analyse the spectra and give the results.

The only test available is sensation at present, but this is unmistakable, because, in addition to the burning feel of 140° Fahrenheit, there is a peculiarly unpleasant sensation even in the shade, whether it is that of a tree, an umbrella, a thin tent, or even a walled room with a window, if there is no veranda. This can only come from invisible rays to which all but the thickest coverings are pervious, and which the skin and tissues admit freely.

European "colonists" are, happily for themselves, unknown in India, and the race would immediately die out, as it is only by frequent visits to temperate climates that a European can preserve health. But if they did exist it is open to doubt if a white skin would ever become black. It is commonly supposed that the Black Jins of Cochin are converted Hindoos. The difference that a change in dress and diet makes in these is singular, many being termed Portuguese, for example, who are pure natives descended from converts whom the Portuguese for the most part made forcibly.

As a rule, the higher the caste and the higher in the scale a native of India is, the whiter he is; and the lower the caste and hotter the mean temperature of the place, the blacker. But this is not invariably the case, as the outcasts who work in leather in Upper India are rather lighter than some of the Brahmans. However, latitude has most effect, and wherever the sun is hottest all the year round the blacker the natives, down to the equator of heat shown on the atlases. The configuration of the country, however, shows that the shades of colour are due to successive waves of conquest from the north, and the Northern Asiatics, who were nearly white at first, degenerate the farther south they come, and are unfit for labour. A blackness of skin, therefore, confers an immunity from the effects of the sun, so that those having it can labour in the heat in a way that would soon cause the lighter races to give in.

Black radiates quicker than white, and though black coats are by no means unknown to Europeans in India, who are as often in those as in coats of any other colour, the black skin of the labourer would throw off accumulated heat much more quickly than if white, and perhaps in a ratio worth calculating. This must be one of the reasons; and it may be noticed that the exterior of buildings is frequently tinted a slate colour with this view, in India, instead of being whitewashed.

Still a more ready dissipation of heat is not the only advantage imparted by a pigmentary blackness in the human skin; and it is to be inferred that the real protection consists in there being a few of the invisible solar rays of the spectrum in tropical light injurious to man, which nevertheless possess unusual

penetrative energy, and go through a thickness of what are ordinarily considered opaque substances, but which are intercepted by the contents of the epidermic pigment cells largely developed in the African, a little more sparingly in Hindoos, and not absolutely wanting in the sunburnt excursionist or sportsman in our own country.

The Australian will tell you that he has done hard work—in a shade temperature of 100°—in the sun in a light wideawake and not felt exhausted; while continuous labour of some hours in much less heat—75° in the shade and exposed to the sun—in Hindostan would be simple destruction of the European's powers of exertion with all a Bond Street hatter could devise on his head. Equator of Heat, India, October 1

The Distribution of Scientific Works Published by the British Government

I HAVE read Dr. Valentine Ball's letter in your journal of October 30 (p. 634) expressing his astonishment that the scientific Reports of the British Government are not presented to the leading American scientific institutions. It may surprise Dr. Ball to learn that the Treasury recently refused to present one of the largest scientific libraries in Dublin with copies of the *Challenger* Reports on the ground that their "free list" was too limited! G. F. B.

A NEW METHOD OF HEATING IN THE REGENERATIVE GAS FURNACE

DURING the present age, which may be called that of Electricity, the sister science of Heat is not receiving so much attention at the hands of the natural philosopher as it did formerly. But still there remain some scientific men who are giving a life-long attention to it MM. Hirn and Berthelot in France, Herren Clausius, Helmholtz, and Frederick Siemens in Germany, Mr. Joule and Sir William Thomson in this country. During the late Sir William Siemens's lifetime, the one brother worked here in the science of Heat, the other in Germany, and the work of both was applied everywhere; now Mr. Frederick Siemens works alone, and, from the recent evidence of that work, it promises to play an important part in the economical application of fuel. Mr. F. Siemens has recently had an opportunity given him of bringing his views forward in this country, having read a paper at the Chester meeting of the Iron and Steel Institute on a new method of heating in the regenerative gas furnace, in which he treated the practical side of the question, whilst in the discussion of the same paper he gave his views on the theory of the subject. Mr. F. Siemens's investigations have led him to the conclusion that combustion can only be perfect, and be maintained perfect, if the space in which it takes place is sufficiently large to allow the gases to combine out of contact with solid materials. Having proved by actual experiment that solid substances interfere with the formation of flame and that flame injures solid substances with which it comes in contact, he brings forward an hypothesis to account for the phenomena. According to the electrical hypothesis, which Mr. Siemens prefers, flame is the result of an infinite number of exceedingly minute electrical flashes, the flashes being due to the exceedingly swift motion of gaseous particles, and a solid body which opposes itself to these flashes is cut by them, whilst, the motion being more or less arrested by the solid body, the flame is damped.

Another important deduction from these investigations is that combustion should be considered in two stages or periods, which may be respectively called active and neutral. In the first the purely chemical combination of the gases takes place, during which, as soon as the temperature of ignition has been reached, the whole of the heat of the highest possible intensity is produced, of which a large portion is given off by radiation, whilst in the second the temperature having fallen in the proportion of the heat given off by radiation, the remainder of the heat which is no longer of an active character, is best transmitted by conduction. For the purpose of utilising this portion of the heat, as well as for raising the temperature of the gas and air before combustion, the regenerators are requisite which form an essential feature of all furnaces worked at an intense heat on the Siemens principle, care being taken to design the furnace so that the gases shall have combined perfectly before the products of combustion are allowed to pass away.

Mr. Siemens in applying his investigations to practice insists that flame must not be allowed to impinge upon bodies to be heated, but must simply heat the bodies by radiation, and furnaces must be so constructed as to allow the flame to develop out of contact, not only with the substance on its bed, but with the walls and roof of the furnace itself; it thus follows that large furnaces must replace small ones, and to meet the objection that the loss of heat into the atmosphere must increase in the proportion of the area of the furnace, Mr. Siemens explains that the heat developed in the furnace increases in a much larger ratio than its increase in area, because flame radiates in every direction from every portion of its entire volume, while a solid substance radiates from its external surface only. The details of construction of metallurgical and glass furnaces and of steam-boilers are given in the paper in question, and need not be considered here; the main point is that furnaces heated on the radiation principle have been proved both in Dresden and at Landore to have been economical of fuel, whilst the saving in the materials treated from reduced oxidation and in the construction of the furnace has been found to be very great.

There is another point of view of this important question which is daily demanding and commanding more attention, and that is the abatement of the smoke nuisance. As is well known, smoke is but incomplete combustion, and the only way to get rid of it is not to produce it. Mr. Siemens insists that this can only be effected by not permitting flame to touch any substance whatever so long as it exists in the active condition; for, just as carbon is precipitated upon a glass rod put into an ordinary gas flame, so is it with any flame whatever its temperature; but the greater the difference of temperature between the flame and the body brought into contact with it the greater will be the amount of smoke produced. Mr. Siemens tells how in Dresden he succeeded in extending his works, without the production of smoke, by the application of the system of heating he recommends, and trusts that here also not only may smoke be abated, but that the public may also derive benefit by manufacturers being able to supply goods at cheaper rates owing to being able to economise their fuel and the material heated within the furnaces as well as that of which the furnaces are constructed.

THE PRIME MERIDIAN CONFERENCE

THE greatly extended and ever increasing intercourse, both commercial and scientific, which has grown up between different nations in modern times has naturally caused especial attention to be drawn to the question of assimilation of the different systems of reckoning employed. Weights and measures and money have been already dealt with more or less successfully, but always with steady advance in the direction of unification. More recently, and in like manner because of practical difficulties and inconveniences, unification of the methods of counting longitude and time has in its turn become a question pressing for solution by the establishment of some international agreement in regard to all matters relating thereto.

The subject became first systematically discussed at the Conference of the International Geodetic Association

held at Rome about a year ago, and the recommendations then formulated have since been further considered at a special International Conference recently assembled at Washington, the delegates at which, in some cases scientific men, in others the ambassadors accredited to the United States, were instructed by their respective Governments specially for the settlement of the questions of a prime meridian and universal time. Their final recommendations on the principal points involved are now before the world.

Unlike the related question of weights and measures, that of time becomes to a great extent simplified by the circumstance that no assimilation of units is necessary, since in the reckoning of time there exists one natural unit which already all nations alike employ, that of the solar day, divided in all centres of civilisation into twenty-four hours, each hour into sixty minutes, and each minute into sixty seconds, and reckoned generally from midnight to the midnight following. In the business and concerns of any single centre no anomaly arises, but if we travel to the east or west of our centre, say from Greenwich, we change—not our manner of counting time—not our unit—but only the zero from which we begin to count, that is, midnight in our new position will occur at a different absolute time. Thus midnight at Paris occurs nine minutes of time before midnight at Greenwich, and this difference between the natural time of the two places is their difference of longitude.

The practical navigator carries with him charts on which longitude is marked as reckoned from some particular meridian. Whilst some nations use the Greenwich meridian, others employ that of their own capital city or observatory, so that longitudes become differently reckoned on the charts of different nationalities. This, as regards practical navigation and in many questions of geography, was one inconvenience.

For many years all clocks throughout Great Britain have been regulated to Greenwich time. This causes no appreciable inconvenience in other parts of the country, because, on account of its small extent in the easterly and westerly direction, the natural time at any place (as referred to the sun) differs so little from Greenwich time that no violence is done to our conceptions of morning and evening as referred to the clock, whilst the advantage of having one standard time throughout the country is, in these days, enormous. Similarly the time of Paris is used in France, and so on. In the United States of America a more natural division into sections has been made, each having its own standard time, about which we shall have more to say further on. The standard time thus used throughout each particular country or section of country, whilst satisfying entirely internal needs, fails, on account of the difference existing between the standard times of adjacent countries, to meet international requirements, not only in questions of scientific interest, but also in matters commercial. The standard time counted in any district must continue to regulate its civil affairs, but for the efficient control of those of international concern, such as the railway, telegraphic, postal, and steamship services, an extension of the same principle to the whole globe by the establishment of some system of universal time, for use in conjunction with local standard time, became very desirable, for although such universal time could not be suitably employed in the ordinary way, the importance of its adoption in matters of international interest had become abundantly apparent. One other point. In civil affairs the day is counted from midnight, whilst astronomers count from the noon following, rendering troublesome conversions from one system to the other frequently necessary. These were other questions requiring consideration.

Clearly therefore the time had come for promoting a better understanding on points of this kind. The recommendations of the Roman Conference briefly stated were, that the initial meridian should be that of Greenwich, corresponding to the point midway between the piers of the Greenwich meridian circle, since such meridian fulfilled all the requirements of science, being already that most used and best likely to be generally accepted; also that longitude should be counted from the meridian of Greenwich in one direction only, from west to east, that is to say, the longitude of Berlin would be 0h. 54m., and that of Dublin 23h. 35m. The Conference further recommended, for purposes for which universal time would be convenient, that the universal day should commence at mean noon of Greenwich time, and be counted from 0h. to 24h., as was proposed in America in the year 1879 by Sandford Fleming and Cleveland Abbe, a proposition which had received the support also of well-known astronomers. It may be added that a proposition to assimilate the astronomical day with the civil day, and adopt it as the universal day, being scantily supported, was lost.

So far as regards the Roman Conference. Their proposals served to indicate the points requiring consideration, so that, attention having been thus directed to the whole question during the year since elapsed, the delegates attending the recent Washington Conference had full opportunity of forming deliberate opinion thereon. We are not yet in possession of the full discussions of the Conference, but we know their decision on all essential points. The recommendation of the Roman Conference that the meridian of Greenwich should be the universal prime meridian was confirmed. But on the question of reckoning longitude the Conference resolved that it should be counted from Greenwich in two directions up to 180°, the east longitude to be *plus*, and the west longitude *minus*, in this particular departing from the recommendation of the Roman Conference. The Washington Conference also disagreed with the resolution of the Roman Conference in regard to universal time, declaring the universal day to be the mean solar day to commence for all the world at the moment of mean midnight of the initial meridian, coinciding with the beginning of the civil day, and to be counted from 0h. up to 24h., a proposition which, as already mentioned, had been debated at the Roman Conference. Protocols were approved which will be made the basis of an international convention fixing Greenwich as the prime meridian.

Practically, therefore, the recommendations are:—

(1) That the prime meridian be that of Greenwich.

(2) That longitude be counted from this meridian in two directions up to 180°, calling east longitude *plus* and west longitude *minus*.

(3) That the universal day be the Greenwich civil day, commencing at midnight and reckoning from 0h. up to 24h.

After full discussion at two Conferences we may believe that, regarding scientific requirements on the one hand and practical considerations on the other, the conclusions arrived at are the best which, under the circumstances, were possible. We may now proceed to consider in various ways their practical bearing.

First, as affecting matters nautical and geographical. By the adoption of Greenwich as the prime meridian (which, if that of any one place were to be selected, was clearly from its extensive use the one which had by far the strongest claim to consideration), and by the retention of the system of counting longitude east and west up to 180°, all British maps and charts (already extensively used by most other nations) and all tables of longitude as hitherto prepared remain still in harmony with the recommendations of the Washington Conference. And since foreign nations thus so largely use charts which refer to Greenwich, the use of this meridian is likely in time to become universal. This being so, some labour of calculation might also be saved, for, considering that large portions of the existing astronomical and nautical

ephemerides of different countries are prepared mainly for the purposes of navigation, and that these ephemerides are calculated generally for different meridians, should charts on which longitude from Greenwich only is counted come into universal use, such separate calculation would become unnecessary. A certain uniformity has already been arrived at, our own *Nautical Almanac*, the American *Ephemeris*, and the German *Nautical Almanac* being all alike calculated for the Greenwich meridian, with the result, however, that now a mass of information for navigators—practically identical information—is repeated in three separate works. This hardly saves labour, and it seems not unreasonable to suppose, as regards the needs of navigators, that one book might in some way be made to serve for all.

It may be remarked that the counting of longitude in both directions up to 180° instead of continuously from 0° to 360° has, as regards navigation, advantages. Because, when counted in both directions, a navigator or traveller, in journeying round the world and changing his reckoning of longitude from east to west, or from west to east, as the case may be, at the same time that he makes the change of one day in his date (of course somewhere near the 180th degree of longitude) will always correctly produce the Greenwich date, necessary when the *Nautical Almanac* has to be referred to, by simple combination of his local time and longitude, whereas if longitude be reckoned from 0h. to 24h., and the navigator makes, as before, the change of one day in his date in the usual way at or near the 180th degree of longitude, which he must do if his date is to be in harmony with that of the countries which he will next approach (America if voyaging east, Australia if voyaging west) it will be necessary, when between longitude 0h. and 12h. west, after subtracting the longitude (always east) from the local time, to further add one day, in order to produce the correct Greenwich date. It will be understood that a chronometer, though showing Greenwich time, does not indicate the *day*, only hours and minutes, &c., so that a voyager has to depend for the correct Greenwich date on his own numeration of days and a proper consideration of his longitude.

Then as regards the question of universal time, first in relation to our own country. Greenwich mean solar time, or Greenwich time reckoning from midnight and counting from 0h. to 24h., being adopted as the international universal time, is such as is shown on all railway clocks throughout Great Britain, excepting that the railway clocks require twelve hours to be added to their indications during the afternoon hours, that is, 1h. railway time is 13h. universal time, and so on. Thus the time of any circumstance or phenomenon occurring in Great Britain will be properly given in universal time by dropping the suffix a.m. or p.m., and in the afternoon adding twelve hours. October 20, 9h. a.m., and October 20, 3h. p.m., become in universal time October 20, 9h., and October 20, 15h. But independently of this the counting of hours from 0h. to 24h. is desirable also in civil affairs generally as being in itself explicit, and rendering unnecessary the distinguishing a.m. and p.m. If clocks, when convenient, were constructed so as to indicate hours in this way, instead of counting from 0h. to 12h. twice over, it would tend to familiarise people with the 24-hour system without at all forcing its use; or the division into twelve might be retained in clocks and watches, and two sets of hour figures engraved. The use of the system will, however, extend on account of various practical advantages. The plan could be introduced with benefit into railway time-tables, especially those dealing with long routes, in which the distinction between morning and afternoon is far from explicit. Morning hours would be 0, 1, 2, &c., afternoon hours 12, 13, 14, &c.

In other countries in which, as in England, the standard time employed is that of some one city or observatory, such time similarly reckoned from midnight, and counted from 0h. to 24h., would be used for all internal affairs. But to give the epoch of any occurrence in universal time it would be necessary to subtract from the time noted the longitude east from Greenwich of the city or observatory whose time is used, or add thereto the longitude west.

Whilst it is absolutely necessary for the regulation of the internal affairs of a country that the time of one meridian should be employed throughout, as in Great Britain, it is also important that the time so used should not be violently out of joint as it were with the natural day. In our diminutive Great Britain no inconvenience arises, as has been mentioned; but in America, owing to the vast extent of the country in an easterly and westerly direction, it becomes necessary to make some arbitrary division. The railway companies of Canada and the United States, for regulation of the time on railways, have solved the difficulty in the following way:—Four different meridians being selected, those of 5, 6, 7, and 8 hours west of Greenwich, four separate districts are created, in each of which the time of one of these meridians is employed. By this means a great step in the unification of time has been made, because on this plan the minutes and seconds in each district are the same as the minutes and seconds of Greenwich time, and also therefore of universal time, the actual universal time in each district being at once found if required by simply adding 5, 6, 7, or 8 hours respectively to the local standard time.

But it may be asked, if the surface of the earth be divided into districts counting in each, for use in civil affairs, the time of some particular place or meridian contained therein, what is the particular need of universal time? The question has been already touched upon; but let us illustrate. A telegram received at a telegraph office in India in the afternoon for transmission to London would arrive in the morning, according to the local time reckoned at these places. Is there nothing here that for some considerations it might not be desirable to arrange differently? Would it not be useful to have the power of indicating universal time in conjunction with local time, if necessary? And so also in other affairs. And in matters of science, especially the observational sciences, the introduction of universal time for use when required would be in many ways beneficial. When an astronomer has gathered together for discussion a long series of observations of, say, a new comet, made perhaps at many different observatories, one of the first things that he has to do is to reduce the times of observation to that of one meridian. Again, observations of solar and other physical phenomena cannot be properly collated unless the times are reduced to one standard. Or, in magnetism, on the occurrence of a great magnetic storm, how much would the comparison of the records obtained at different places be here also facilitated by the use of universal time?

There might be some disinclination as regards fixed observatories to give results in universal time, because of the fractional difference of longitude. But in civil affairs, admitting the practicability of adopting the system inaugurated in America, of forming districts and employing as local standards of time secondary meridians distant from Greenwich by integral numbers of hours, as before described, the indication of universal time in conjunction with local standard time becomes a matter of great simplicity. Objection may be made to the system because of the variation, amounting to half an hour, which would exist, between the natural day and the clock time employed, at the extreme borders of the districts so formed, but the Greenwich time long used in Cornwall differs (without reckoning the effect of the equation of time) twenty-three minutes from the natural time without inconvenience arising. Indeed, taken in conjunction with what has been done at the Washington Conference, the

scheme is, outside of the Conference, the first really scientific step that has been taken in the practical unification of time throughout the world. Whether the number of meridians might be doubled is perhaps a question, but, as it stands, the scheme is extremely simple. For since the minutes and seconds counted in the several districts are the same as the minutes and seconds of Greenwich or universal time, the mere addition of another hour hand to the clocks in common use, placed in the proper position and travelling with the ordinary hour hand, would enable either local standard time or universal time to be read off at pleasure from the one clock. The ordinary hour and minute hands might be black and the additional hour hand of a lighter colour, in which way sufficient distinction would be produced. Such clocks should show hours from oh. to 24h. Or the conversion might be made in other ways. Referring to the American division before described, all entries might be distinguished as "local standard time," and a precept added to indicate that, to obtain universal time, 5, 6, 7, or 8 hours must be added, as the case may be. Or denoting the times as "standard times on the 5th meridian west," &c., the variation from universal time is at once shown. The reader will probably now have grasped the special merit of this system, the readiness with which either local time or universal time can be together indicated.

It may be interesting to show how the American plan of division into districts defined by hourly meridians would work if applied generally to the countries of the world. A scheme in regard to some of these countries is herewith annexed.

Countries	Longitude from Greenwich of meridian to be employed for local standard time	Local time at which universal date changes
Great Britain, France, and Spain	oh.	Midnight
Norway, Sweden, Germany, Austria, and Italy	1h. east ...	1h. morning
Western Russia, Turkey, and Egypt	2h. ,, ...	2h. ,,
Western India	5h. ,, ...	5h. ,,
Eastern India	6h. ,, ...	6h. ,,
Western Australia	8h. ,, ...	8h. ,,
South Australia	9h. ,, ...	9h. ,,
Victoria, New South Wales, and Queensland	10h. ,, ...	10h. ,,
New Zealand	12h. ,, ...	Noon
California	8h. west ...	4h. evening
Eastern America (Washington)	5h. ,, ...	7h. ,,

In east longitude decrease, and in west longitude increase, the local standard time by the hours of longitude to obtain universal time.

The scheme in fact resolves itself into adopting in any country the time of the nearest integral hourly meridian. Russia would become divided in some such way as America. In each case the minutes and seconds of local standard time would be similar to those of Greenwich or universal time, change of the hour, according to the precept given at the foot of the table, converting the local standard time at once into universal time. We are quite aware that a scheme of this kind can scarcely be expected yet to take practical shape, but it seems well to point out generally the direction in which with the least inconvenience a satisfactory solution of the problem of counting universal time in conjunction with local time may be possible.

The right hand column of the preceding table indicates, in regard to the universal day proposed by the Conference, the hour of the local civil day at which, in the several districts, the universal date would change, the civil date of course changing at midnight. It will be remarked that in all countries in east longitude as far as Australia, the change of universal date (following that of the same civil date) takes place generally in the morning hours, before the business hours of the civil day, the universal and civil dates being then in accord until civil midnight. In America the universal and civil dates are in accord from civil midnight until towards the next evening when the universal date changes (before change of the same civil date). In all these cases the change of universal date occurs at an hour well away from business hours. Only in New Zealand would there be inconvenience, the change of universal date occurring at civil noon, twelve hours after change of the same civil date. Knowing approximately the local time at which the universal date changes, a clock fitted with an additional hour hand in the way described would indicate at once the precise time of change.

The resolution of the Washington Conference further expresses a hope that as soon as practicable astronomical and nautical days may be arranged everywhere to begin at mean midnight, which would simplify any desired conversion into the proposed universal time. Passing by the nautical aspect of the question we may remark, that astronomers as a rule count their mean solar day of twenty-four hours from noon, commencing twelve hours later than the civil day of the same date, and the day is thus understood in all published observations and astronomical works. There is another consideration, somewhat fanciful perhaps, that astronomical observations being taken mostly at night it seems objectionable to make a change of date at midnight in the middle of a series of observations; but this carries now with it much less weight since attention to solar phenomena has so increased observation by day. It was perhaps felt at the Conference that the local civil and astronomical days should correspond as a matter of convenience in itself, and as simplifying the relation of both with the proposed universal day, thus promoting the use of the latter as might become convenient, either in civil or scientific affairs. To effect such correspondence, one of the days had to be altered, but since any proposition to change the local civil date at noon could not be seriously entertained, it was better that the astronomer should assimilate his day with the civil day. Indeed it was formerly the practice in France to employ the astronomical day, commencing at midnight, in the construction of planetary and lunar tables.

The proposed change in the time of commencement of the local astronomical day will involve some present awkwardness from the circumstance that the different astronomical ephemerides are calculated for astronomical time as hitherto reckoned, in addition to which our own *Nautical Almanac* is prepared several years in advance. Temporary inconvenience more or less there must be, but the new reckoning, when fully established, will be found to possess some distinct advantages. As concerns the Royal Observatory at Greenwich, the Astronomer-Royal proposes to adopt the recommendation of the Washington Conference by commencing on January 1 of next year to count the astronomical day from the midnight preceding the nominal civil date, thus bringing the Greenwich astronomical day into correspondence with the Greenwich civil day, which is the universal day of the Conference; he proposes further to alter the indication of the public clock at the entrance gate of the Observatory, so that oh. of the clock shall also commence with midnight: all being counted from oh. to 24h. The time reckoned within the Observatory and that shown on its external wall will then be in accord. So far the astronomer. If, in addition, the civilian would relinquish the use of the confusing a.m. and p.m., and instead count the hours also from oh. to 24h., beginning with midnight, all parties would then be using the same system for reckoning both days and hours of the day.

WILLIAM ELLIS

THE ILLUMINATED FOUNTAINS AT THE HEALTHERIES

NOW that the most successful of International Exhibitions has been closed, we are able to give the final result of the accumulated experience that has been obtained in connection with the working of the illuminated fountains, which excited unqualified admiration. Even on the last night we believe new experiments were tried, and next season these fountains are likely to be finer than ever.

"I wonder how it is done?" This was one of the remarks most frequently heard in the dense crowd which nightly surrounded the large fountain at the Health Exhibition, watching the many party-coloured jets of water as they rose and fell with an ever-varying combination of brilliant hues. It is believed that an account of the means employed to produce these gorgeous and novel effects, and of the way in which the water and lights were managed, cannot fail to interest our readers.

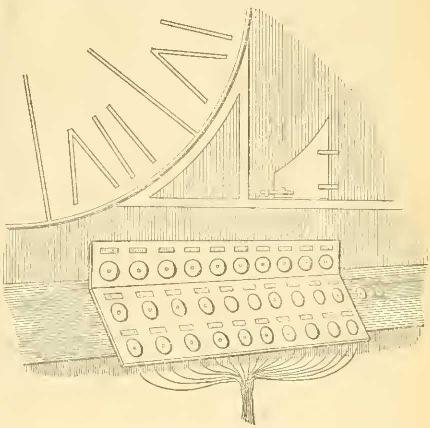
The water-supply is obtained from the West Middlesex Water Company by means of a nine-inch main, which is connected to one of their mains in Kensington Gore. As the water is paid for according to quantity used, it has to be measured, and in order to effect this with as little loss of pressure as possible, the water is passed through three eight-inch Tyler meters, which are to be seen at the north-west corner of the grounds in the vicinity of the fountains. These meters are connected at each end by a four-way junction piece to the nine-inch main, and they were afterwards supplemented by a twelve-inch one on a separate branch. From the four meters the main passes under the water into the central chamber in the basin, and it there branches into three pipes, two of nine inches diameter, and one of six inches. The two nine-inch pipes go round the two sides of the chamber, which is twenty feet square, and are connected together at the opposite side, thus forming a loop round the chamber. Off this main are taken the supplies to the four rings of jets in the basin, and also for the jets on the top of the chamber, each ring having two supplies at opposite sides in order to equalise the pressure. The third branch, which is in direct continuation of the main from the meters, is gradually reduced to three inches, and supplies the centre jet only.

All the supplies are furnished with screw valves worked by hand wheels. The jets on the top of the chamber consist of the centre jet and four other jets placed at the four corners; each of these jets is surrounded by a ring of twelve small jets, and there are also four dome and convolvulus jets placed between the corner jets. The supply to the four corner-jets is controlled by a plug-valve, so that they can be rapidly turned on and off. It is by this means that the jumping of the centre-jet is produced, the momentum of the water flowing through these jets being sufficient, on the sudden closing of the valve, to jerk the centre jet thirty feet higher than the point which it reaches from the pressure of the mains alone.

In order to light up the various jets on the top of the chamber, five circular sheets of glass two feet in diameter are let into the flat roof of the chamber, one under each jet. The pipes leading to these jets go through the roof close to the edge of the glass, and are then bent over it and upwards again, so as to bring the jet itself exactly over the centre, and it is under these panes that the lighting apparatus is placed. This consists of a simple bracket lamp with rack and pinion worked by hand for feeding the carbons, and a third-order holophote lens twenty-two inches in diameter. The carbons are placed at an angle of about 20° with the horizon, and the bottom carbon is the positive one, in order to have the crater turned upwards. The axis of the top carbon is also slightly above that of the lower one, although parallel to it. The carbons are eighteen millimetres in diameter, and the current is about sixty amperes. The five lamps are connected in parallel. Each lamp is inclosed in a case to protect the men from the light. Above each holophote is placed a frame with five grooves, in which run five frames containing the different coloured glasses by which the various colours are produced.

When first erected the jets were provided with glass bottoms, and a small lens was placed above the holophote so as to concentrate the centre portion of the ray on the interior of the rising column of water. It was however found that this arrangement considerably reduced the height of the jet, on account of the eddies produced in the chamber at the bottom of the jet, and also diminished the amount of light thrown on the spray, and it was therefore abandoned.

The principle of interior lighting of a stream of water was applied to three jets from the top of the Corinthian columns erected on each side of the statue of the late Prince Consort, and for this purpose two two-inch pipes were taken up each column, and connected with a cistern from which issue three jets, each illuminated from behind



by an electric lamp with twelve-millimetre carbons and twenty-ampere current. These lamps are in parallel arc on the same circuit as the large lamps in the centre chamber, suitable resistances being inserted. It was found that the two supplies provided did not allow of a column of water of sufficient diameter being thrown from each jet to prevent its being broken up by the wind, and as it was impossible to increase the supply while the Exhibition was open, these effects were rarely used. The current for these eleven lamps, amounting to 420 amperes, is generated by a compound shunt-wound Simens B_2 machine placed in the electric light shed. The armature of this machine is built up of copper strips with spaces between, and is thus especially adapted for the work it has to do, which at times is very severe, as, the lamps being hand-fed, the arc is not struck as rapidly as in an automatic lamp, and the machine is therefore short-circuited for an appreciable space of time on starting or relighting any lamp. The electromotive force at the machine is eighty-four volts. From the machine the current is conveyed to the small hut near the meters by two well-insulated cables of nineteen strands of No. 12 copper wire, and from the hut it is distributed to the island lamps by an insulated cable of nineteen No. 10 wires

inclosed in a lead pipe, and to the columns by two cables of seven strands of No. 12. A separate return cable runs from each lamp to the hut, where it is connected to the necessary resistances, made of strip iron, and from there back to the dynamo through two cables of nineteen No. 12's. There is altogether very nearly a ton of copper in the various leads and branches. Besides these leads the centre chamber is connected to the circuit of the Sun light machine, so that, should any accident occur to the main circuit or machine, Sun lights could be substituted for the hand lamps.

As the falling spray cuts off the light from below when the jets are at their highest, a light is placed in the top of the clock tower to illuminate the top of the jets. This light is a focus-keeping Siemens automatic lamp, and takes a current of fifty amperes, supplied by a small Crompton-Burgin machine. The lamp is inclosed in a cast-iron casing swung on trunnions, and in front of it is a fifth-order holophotal lens by Messrs. Siemens.

The various coloured glasses are fixed in frames or sashes arranged with counterweights, in the same way as an ordinary window. Some of the best effects of colour are also obtained by sheets of gelatine, of which a large number are fastened end to end, and fixed to two rollers, so that they can be wound from the one to the other, and thus passed through the beam of light.

As the men in the centre chamber cannot see the effects they produce, it is necessary to direct them from the outside, and this is effected by an elaborate system of electric bells and disks, which are worked from the clock chamber below the last-described holophote. In this chamber sits Sir Francis Bolton, with a treble row of "pushes" in front of him, all labelled, by touching any of which a corresponding disk or bell is worked in the island. There are four bells—a call bell, an "on" bell, an "off" bell, and a lamp bell—and two indicator boards with eight disks each, and one with four. One board is for the water valves, which are each painted a different colour, with the corresponding colour on the disk, and the second board for the coloured glasses over the holophotes. The disks on the small board refer to the corner lamps, and by their means Sir Francis can direct any colour to be placed over any one of the lamps by touching the push corresponding to the lamp and the push marked with the colour which he wishes to show. The working of the holophote at the top of the clock is directed in the same way.

EXPERIMENTS WITH COAL-DUST AT NEUNKIRCHEN IN GERMANY

DURING the course of the last summer the Royal Prussian Fire-damp Commission has carried out a series of experiments in the Saarbrücken mining district with the view of ascertaining the influence which coal-dust has, alone and in conjunction with fire-damp, in propagating explosions in mines. The apparatus and the mode of experiment were suggested by retired Bergwerks-director and Bergassessor Hilt, of Aix-la-Chapelle, who is a member of the Commission, and the results hitherto obtained have been of the most interesting kind.

The experiments are conducted at the Royal Coal-Mine, König, near Neunkirchen, where there is a blower of fire-damp at a depth of 131 yards below the surface. The quantity of fire-damp given off by this blower amounts to about 0·9 cubic foot per minute, consisting of 86 per cent. of light carburetted hydrogen mixed with air, &c. It has been in existence for the last two years. The fire-damp is brought a distance of 1200 yards in pipes, and collected in a small gasometer whose capacity is 176 cubic feet.

Dr. Ad. Gurlt of Bonn lately called my attention to the fact that over two hundred experiments made with this apparatus on a large scale had proved the correctness of my theory of great colliery explosions (*Proc. Roy. Soc.*, vol. xxiv. p. 354, &c.), and at the same time suggested that a visit to Neunkirchen would be of interest.

Accordingly I proceeded to the scene of the experiments on October 25, accompanied by Mr. Wm. Thomas Lewis, one of the members of the Royal Commission on Accidents in Mines, and we were met there by Dr. Gurlt, who had travelled from Bonn for the purpose, and by Herren Prietze, Nasse, Margraf, and Kreuser, directors and assistant-directors of König Grube and other Royal mines of the neighbourhood. Herr Margraf, under whose superintendence all the experiments are and have been made, has most kindly furnished me with a detailed description of the apparatus and of the experiments witnessed by Mr. Lewis and myself, and I am glad to avail myself of, and shall endeavour to reproduce, his account as nearly as may be, allowance being made for the difficulties of exact translation.

The experiments are made in a horizontal wooden gallery 167 feet long, closed at one end, and having a horizontal branch gallery 33 feet long standing out at right angles to it at a distance of 93 feet from its closed end. Both the main gallery and the branch consist of elliptical rings of double T-iron lined internally with planks 1·6 inch thick, which abut closely together and are grooved and feather-jointed lengthwise. The greater axis of the ellipse stands vertically, and is about 5 feet 7 inches long; the lesser axis is 3 feet 11 inches long. The main and branch galleries are both embedded in the pit-heap to such a depth that the rubbish is level with their top on one side and reaches to three-quarters of their height on the other side. Along the exposed part of the latter side there is a row of windows, thirty-two, in the main gallery, and three in the branch gallery, situated somewhat more than a yard apart. They are formed of sheets of glass about $\frac{3}{8}$ inch thick set in cast-iron frames. There are also a number of openings in the top of the main gallery, one of which, near the closed end, is an ordinary man-hole, which can be closed by a man-hole door like that of a boiler, and serves as a means of ingress and egress. The others are circular, about 9 inches in diameter, and are lightly closed with wooden plugs attached to chains, which act as safety valves. All these openings assist in the removal of after-damp after an explosion.

The closed end of the main gallery is sunk about 3 feet 9 inches into a block of masonry whose dimensions are 12 feet 4 inches long, 9 feet 9 inches wide, and 13 feet high. Seven cast-iron cannon, with a bore similar to that of a shot-hole in hard ground, are built into the block in the position shown in the figure opposite, so that their mouths are flush with the face.

There are two holes near the top, two near the bottom, and three in the middle, grouped symmetrically in relation to the two axes of the ellipse. The middle hole is 37 inches deep by 1·57 inch in diameter; the others are $31\frac{1}{2}$ inches deep by 1·37 inch in diameter. The axes of the two upper and of the two lower holes are placed in such a position that they form the angles of a four-sided regular prism whose apex is situated in the axis of the main gallery at a distance of 16·4 feet from the face. The axes of the three middle holes constitute a bundle of rays which meet at the same point as the last. Wooden hoops projecting inwards from the sides are placed at various distances apart in the main gallery within the first $65\frac{1}{2}$ feet from the face. By fastening cloth diaphragms to these hoops, compartments of various capacity can be formed, that of the first next the face being 705 cubic feet.

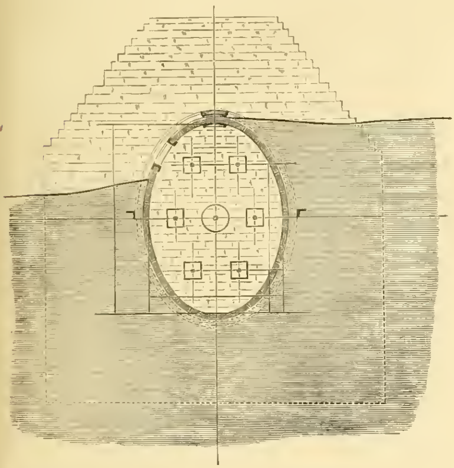
The shots are fired electrically with Abegg's fuses by means of an exploder made by Mahler and Eschenbacher of Vienna. The charge, which consists of 230 grammes, or about half a pound, of powder, occupies a length of 8·64 inches in the central hole, leaving room for rather

over 28 inches of stemming, and 11 inches in the other holes, leaving about 20 inches for stemming.

The coal-dust is strewn upon the floor of the gallery from the face towards the open end in a layer of about 1·17 inch thick immediately before firing the shots. The weight of dust in each ten yards of length is about thirty pounds. It has been found in practice that, notwithstanding the upward direction of their axes, the shots next the floor produce the greatest disturbance of the coal-dust and give rise to longer coal-dust flames than any of the others.

In all the experiments witnessed by Mr. Lewis and myself, *one shot-hole only*, namely, one of the two next the floor, was charged and fired. The charge consisted of 230 grammes of blasting-powder each time, and the tamping was damp clay. Both ends of the branch gallery were closed with a double board brattice 1·96 inch thick.

In the first experiment neither coal-dust nor fire-damp was employed, and the flame of the shot was seen through the windows to be a little over 13 feet long.



In the second experiment a length of 65 feet of the floor of the main gallery was strewn with coal-dust from Camphausen Colliery in the Saarbrücken mining district. The shot gave rise to a loud detonation, and the resulting flame filled the gallery to a distance of $88\frac{1}{2}$ feet. When the thick black after-damp had been drawn off by means of two of Korting's exhausters, placed over two of the safety-holes and worked with compressed air, it was found that the inner brattice of the branch gallery had been broken, and small globules of coke were observed lying on the surface of the remaining coal-dust.

In the third experiment a length of 130 feet of the floor of the main gallery was strewn with coal-dust from Pluto Mine in Westphalia. When the shot was fired, the flame traversed the whole length of the gallery with great velocity, and came out at the open end to a distance of 16 feet, being thus altogether 183 feet long. Notwithstanding the entire absence of fire-damp, this was a true explosion of the most violent kind, and the clouds of after-damp which streamed from every opening darkened the air in the neighbourhood of the gallery for two or three minutes. The brattice at the inner end of the branch gallery had not been replaced before this experiment, and the one at its outer end was broken into small fragments, some of which were thrown to a distance of 115 feet. The flame was also seen to emerge from the branch gallery to a distance of several yards. The coal-dust remaining on the floor after the explosion was covered with a sooty film, in which coke globules were found embedded.

The brattice at both ends of the branch gallery was now replaced, and the floor of the main gallery swept clean as usual. In the fourth and last experiment coal-dust from Pluto Mine was strewn on the floor for a distance of 65 feet from the face. A diaphragm of prepared canvas was fastened in the gallery at the point where the space inclosed between itself and the face amounts to 705 cubic feet.

A volume of $35\frac{1}{4}$ cubic feet of fire-damp was introduced into this space, and complete diffusion was effected by beating the air with cloths. The mixture of fire-damp and air thus obtained is not inflammable or explosive by itself, and shows a cap of only $1\frac{5}{16}$ inch high on the reduced flame of a safety-lamp. The firing of the shot produced a flame 190 feet long, accompanied by a report like a thunder-clap. The inner brattice of the branch gallery was broken, and drawn several yards into the main gallery, but the outer one remained intact.

Some idea of the great force of the two last explosions may be gathered from the following facts:—An ordinary mine railway, beginning on a level with the floor of the main gallery, extends away from its open end in the direction of its length, and ascending at an angle of 4°. An ordinary mine waggon, loaded with iron so as to weigh altogether $15\frac{1}{2}$ cwt., was standing on the rails at the mouth of the main gallery when the shots were fired. When the third shot was fired, it was driven up along the rails to a distance of 23 feet, and when the fourth shot was fired, it was literally hurled along the railway by the force of the explosion to a distance of $52\frac{1}{2}$ feet, being driven off the rails and running on the ground for the last six feet. The boards constituting the end of this waggon next the gallery were broken, but not torn off. A small beam 4 inches square, bolted across the rails at the mouth of the gallery, so as to form a stop for the waggon, was torn from the bolts which held it, and sent flying after the train. Lastly, a shower of stones and debris was raised by the blast which swept out of the mouth of the gallery, and some of the pieces carried upwards of 100 feet.

The foregoing facts appear to me to be well worthy of the attention of all who have any interest in the prevention of explosions in mines. W. GALLOWAY

FLOWERS OUT OF SEASON

THE untimely flowering of trees and shrubs, like the occurrence of the extraordinary gooseberry, is a subject which crops up at such regular intervals as almost to belie the epithet applied to it. Nevertheless, the very frequency of the comment is an indication that the matter is ill understood.

The ordinary time-rate for the production of new cells, new leaves, new flowers, and so on, varies as we see within wide limits. Equally obviously those limitations are imposed by the conjoint effects of inheritance and of external conditions, such as climate or food, or both. An annual plant rushes through its life in hot haste as it were: save and except in the seeds of such plants there is comparatively little building up or maturing of new tissues to be done, and proportionately still less stores of potential food to be accumulated. If, on the one hand, the requirements of such plants are less than in the case of perennials, their exigencies are, on the other hand, more pressing. What they take from the soil, or atmosphere, what power they derive from solar light and heat, must be got quickly or not at all. One illustration of this is afforded by the paucity of annual species in the Arctic regions or at high altitudes. Neither heat nor light is absolutely deficient in such situa-

tions, but the length of time during which they are available is too short to allow annuals to profit by a sufficiently large aggregate to enable them to mature their seeds. Before they can accomplish their purpose, they are overtaken by frost and their activity is put a stop to. The energy of perennials, it is true, may be checked in the same manner, but they have been enabled, before the evil day arrived, to lay up stores of nutriment available for use when the increasing heat and light of the following year shall once more quicken their activity. The work to be done is spread over two or more seasons instead of one, and the chances of success are thus correspondingly enhanced. But if we suppose the conditions to be uniformly and continuously favourable, the abrupt cessation of growth will no longer be manifest, the annual will cease to be an annual, the perennial will not die down in winter, the growing points of the buds will not incase themselves in scales, vegetation will be continuous. Such halcyon conditions find their nearest realisation in moist equatorial climates like that of the Malay peninsula and adjacent islands. But even there the realisation is not perfect. Something happens to disturb the balance; and even if the conditions are generally uniform there is always the idiosyncrasy of individual plants to form a disturbing factor. Again, such conditions, though favourable to the continuance of vegetation, are less propitious to the establishment of fructification. The formation of stem, leaf, flower, even of fruit, is one thing, the maturation of the seed and of the embryo-plant within it is another; and the conditions propitious to either are correspondingly different. The ripe seed makes in proportion larger demands on the plastic matters formed as a result of metabolism, and has almost invariably the same composition according to its species, but this cannot be said with equal truth of any other part of the plant.

Again, the conditions for growth, that is, mere increase in bulk, are different, in degree at least, from those which favour progressive development or metamorphosis. Speaking in general terms, it may be said that vegetation approaches its end where fructification shows signs of commencement. There is indeed no fixed line of demarcation to be drawn, but while morphologically there are gradations and intermediate forms, physiologically there are also transitions, and periods of instability. It is easy to understand how this happens, and how it is the divergences are not greater. These matters indeed partake so much of the nature of truisms, that some apology might almost be needed for insisting on them, were it not that they are absolutely essential for the due comprehension of the phenomena of untimely blooming.

It is also desirable to draw attention to the fact that there is naturally a wide range in the period during which vital activity manifests itself even in individuals of the same species, and as these individuals vary in colour, stature, &c., even when derived from the same stock, so others may vary in their "time-rates." This is specially noticeable in the case of the horse-chestnut, and is perhaps more often manifest in the form of precocious development in spring than in that of tardy growth in autumn. In most cases the plant has to attain a certain age before it produces flowers, but occasionally we find individuals so precocious that they are scarce out of the seed before they burst into flower. A cocoa-nut has thus been seen in flower while the husk of the fruit was still attached to it. Gardeners, according to their requirements, have freely availed themselves of these individual differences by selecting for perpetuation late or early varieties. The whole subject of the "chronometry of life," it may here be mentioned, formed the text of a valuable lecture by Sir James Paget, at the Royal Institution, many years ago.

Cases of unseasonable blossoming may be ranged under three heads, according as growth and development are: (1) prolonged beyond the ordinary time; (2) premature or manifested aforetime; (3) renewed after a short interval of arrest. Categories (2) and (3) differ in detail rather than in essence, as will be explained further on.

Taking the cases of continuous or prolonged growth first, it is easy to see that many of them are due to a continuance of favourable conditions. A long spell of summer without excessive heat or drought will insure a longer period of blooming; flower will succeed to flower so long as the weather and the natural changes in the tissues of the plant, according to age, are held in abeyance. How small are the exigencies of some plants in these matters may be illustrated by the fact that there are few days in the year when a daisy or a white deadnettle may not be found in bloom, at least in the southern half of England. It is necessary, however, to introduce some qualification, because one has only to look into one's garden to see that in spite of apparently favourable conditions many plants are not to be induced to continue blooming. Although in duration perennial, in the matter of flowering they behave as annuals. Something in their organisation forbids the prolongation of the blooming period. That this is so is at least rendered highly probable by the circumstance that the same reticence is exhibited under cultivation. As an illustration of an opposite character, may be mentioned the prolongation of the blooming period even under relatively adverse circumstances which has been brought about by the art and selection exercised by the gardener. Take roses, for instance, only one of many that might be cited. Our fathers had to be content with what we now call summer roses, roses of great beauty and exquisite fragrance, but which they must have wept to see "haste away so soon." Nowadays, the case is very different, there is a whole legion of so-called "hybrid perpetuals" marked in the catalogues of the nurserymen as H.P. By their agency a second crop of roses is assured, while some will continue in favourable seasons to expand their blooms in succession up to Christmas. This prolongation of the flowering season has been brought about by combining by means of hybridisation the robust qualities of European roses with the continuous blooming tendencies of the Indian rose. Many varieties of pear, the common laburnum, the Wistaria, Weigela, the hybrid *Berberis stenophylla*, some rhododendrons, currants (*Ribes*), exhibit this phenomenon, the flowers being produced on the ends of more or less prolonged shoots, as strawberries under like circumstances produce their flowers on the ends of the "runners" of the year.

The premature development of flowers in autumn has a better title to be called unseasonable, because the phenomenon is really due to the unfolding of flowers which, under ordinary circumstances, would remain passive till the following spring. There is not, as in the former case, a new formation or a continuous growth, but merely what the French appropriately call *fleuraison anticipée*. And here for a moment it may be allowable to call attention to an essay of Linnæus entitled *Prolepsis Plantarum*, little read nowadays, although based on facts, and containing much that is still worthy of consideration. For him a flower was a shoot with lateral outgrowths, a morphological conception that would still satisfy a German transcendentalist. But, further, this shoot and its outgrowths were supposed to represent the outcome of six ordinary years' work contracted into one. A flower was, according to this theory, a shoot in which the differentiation of parts instead of being spread over six years was hurried on and completed within one season. For Linnæus leaves represented the work of one year, bracts that of the following one, sepals of the third, petals of the fourth, stamens of the fifth, and the pistil that of the sixth year. It is not necessary to discuss the morphological aspects of this theory, but it is relevant to our present purpose because it emphasises the relation of leaf-shoot to flower—a relation enunciated about the same

time, and independently one of the other, by Wolf and by Linnæus, and thirty years before Goethe propounded a similar notion. Moreover, it brings into prominence not only the morphological relation of shoot and flower, but one manner in which the time of production of the shoot and of the flower respectively may be varied, a subject having an immediate bearing on the question of unseasonable flowering. If, says Linnæus (*Prolepsis*, § iii.), "a shrub which has been grown in a pot, and has borne flower and fruit every year, be transferred to richer soil in a hot-house, it will produce for many years numerous leafy shoots, but no fruit. From which it may be inferred that the leaves are produced from the same source whence the flowers previously sprang, and so in turn what now tends to form leaves would, by this agency of Nature, be converted into flower if the same tree were again placed in a pot so as to confine the roots; hence gardeners desirous of obtaining a more plentiful crop of strawberries, cut the fine roots of the plants in spring before they transplant them, in the hope that they will produce more abundant flowers and fruit." Here we see the same principle laid down as that upon which gardeners act when they wish to secure flower and fruit by cutting off the supplies, and thus making the plant, to a greater degree, dependent on the elaborated reserve stored up in their tissues. This is effected by growing plants in small pots, root-pruning, transplanting, ringing, and other processes, all of which tend to diminish root-absorption, and by disturbing the balance between it and other processes, to check vegetation, and in so far to promote the formation of flower. Charles Martins relates the production on a very large scale of inflorescence on the Agave, in Algeria, as the direct consequence of the excision of the leaf-buds by a troop of French cavalry, who hacked the plants with their sabres as they passed, and thus, by preventing or checking growth in one direction, stimulated it in another. In like manner I have seen flowers produced on the "suckers" of *Ailanthus glandulosa* when the plant was quite young, on the roots of *Pyrus japonica*, and on a sucker of Agave, as the result of injury, probably in all, certainly in some, of the instances.

The frequent production of flowers out of season on newly transplanted trees is accounted for in like manner. But many trees are flowering this autumn which have not been slashed with sabres nor moved by more peaceful weapons. One such tree, a horse-chestnut, I lately (September) saw, in which one limb, and one only, was full of young leaves and flowers, while the remaining limbs were fast losing their foliage. The reason for this partial production of bloom I was not able to divine; possibly it may have had some relation to injury to a certain portion of the root-system in more or less direct connection with the particular branch, but I have no evidence to offer in support of such a guess.

In speaking previously of one modification of unseasonable flowering dependent on activity protracted beyond the customary period, it was mentioned that the flower was in such instances developed at the ends of long slender shoots formed during the course of the summer. In such cases the shoot ends in a flower-bud instead of a leaf-bud as is usually the case. The conditions are no longer favourable for the extension of the shoot, and the energy of growth is diverted to the production of flower. But in the laburnum, in many fruit-trees, such as the apple and pear, the fruits are normally borne on short thick branches called by the gardeners "spurs." These are very interesting physiologically, as possessing intermediate transitional characteristics, such as those before alluded to, between vegetation and seed-production. In form, these spurs are short and thick, with very narrow interspaces between the leaves, and they bear a cluster of buds which ultimately all develop into flowers, or in which the central and terminal one is a leaf-bud. Internally these spurs are soft and spongy, with a great preponderance of cellular over fibro-vascular or woody tissue. The cells are moreover filled with starch. We have evidently here got to do with store-places, analogous to that furnished by the tuber of the potato and other formations, in which food, or matter capable of conversion into food, is stored up for future use at the growing points; in this case for the formation of fruit. Flowers are occasionally produced on these spurs out of due season: the flower-bud destined for a following season bursts into activity this year, affording an instance of a true *fleuraison anticipée*; but more often, according to my observations, when an untimely flower is produced (especially in the apple), it is from the development of a flower in the central bud of the spur, which is usually a leaf-bud as above stated. In such a case, then, we have not only an alteration in the character of the bud, but a change in the period of its expansion. A converse illustration to that just given is afforded by a case recorded by Mr. Berkeley, in which a bud of a walnut, which in the ordinary course of things should have produced a female inflorescence in the following spring, was developed in the autumn as a leafy shoot.

Renewal of growth after temporary arrest, "recrudescence" as it is sometimes called, occurs normally in the pine-apple, Eucomis, Metrosideros, and other plants. Abnormally, I have met with it in *Cytisus nigricans*, the common wallflower, Œnothera, and many others. It hardly differs from the first category mentioned in this note except in the fact that the new growth is the direct continuation of the old and not an entirely new lateral formation. It differs from the terminal bud of a "spur," in that the latter is normal as to position even if developed out of season, whereas in the class of cases now under consideration the activity of the growing point, which usually ceases with the development of the last flower, is exceptionally continued.

One other circumstance deserves mention, and that is the rarity with which true fruit, or at least ripe seed, is produced as a result of these untimely flowers. Sometimes, of course, ripe seed is produced; a plum is before me as I write the seed of which is as perfect, to all appearance, as that of the first crop could have been. But in the majority of the pears and apples which come under one's notice at this unseasonable period, the fruit is there (in the popular sense), but the core, which is in a botanical sense the true fruit, is absent, or, if present, the seeds it contains are usually abortive. Botanical readers will readily see the morphological reason why, and physiologists will recognise that in such cases the deviation from the ordinary course is not so great as it appears upon the surface, and the action of the "environment" is not so potent as it appears to be at first sight.

To sum up: these cases of unseasonable flowering appear to be due either to continuous growth and development, to renewal of growth after a longer or shorter period of arrest, or to the development of a flower-bud in the place of a leaf-bud. What produces these changes? To this no more precise answer can be given than has already been afforded. The absolute nature of the change, structurally and morphologically, depends upon the nature of the inducing causes, and varies accordingly; the degree of change may depend simply on the increased or prolonged intensity of action of the same causes which promote natural growth.

MAXWELL T. MASTERS

NOTES

THE Washington Prime Meridian Conference closed on November 1. Protocols were approved, which will be made the basis of an international convention, fixing Greenwich as the prime meridian.

MANCHESTER is determined to have the British Association in 1886, and its invitation will almost certainly be accepted.

THERE is no truth in the statement which is being repeated so often that Baron Nordenskjöld intends to lead an expedition into the Antarctic regions.

IN a letter from the Sagastyr Meteorological Station on the Lena, dated March 20, and appearing in the last issue of the *Izvestia*, M. Yurgens informs the Russian Geographical Society that twenty-six years ago a mammoth was discovered in the delta of the Lena, twenty-three miles from the station. Its head and tusks had already been taken away by a Russian merchant at the time of the discovery of the body, and the Yakuts of the neighbouring settlement have taken a leg, several ribs for making spoons, as also parts of its skin for straps, and fat for painting their sledges. The body is lying on the right side in the lower part of a crag of alluvial deposits thirty feet high. The interior is said to be quite safe. Dr. Bunge went to the place pointed out by the Yakuts, and undertook regular excavations for a distance of 350 feet, the expedition not being sure that the Yakuts have shown the right place: they consider it a sin to take from the earth what it does not give itself. The work is very hard, the excavations being made in a frozen mass of snow, "as hard as sugar," M. Yurgens says. While the work was at a lull, news was received of another mammoth's body discovered only six years ago on the Moloda River, left bank tributary of the Lena, joining it thirty-five miles above Siktyakh, which has remained still untouched. If the news is confirmed, M. Yurgens will make an excursion to discover it.

IN a subsequent letter, dated April 16, M. Yurgens writes that M. Eigner has made magnetic measurements to the east of the station as far as Ust-Yansk. Full measurements were made at ten places, notwithstanding frosts of $-30°$ to $-40°$ C. Mr. Yurgens will make the same measurements to the west of the station. Preparations are already made for the return journey. Several magnetic instruments had to be packed at the end of April and sent on sledges to Bulun. M. Eigner proposed to leave the station at the same time, while MM. Bunge and Yurgens intended to stay at Sagastyr until June 15.

THE following papers were entered to be read, *Science* states, at the Newport meeting of the National Academy of Sciences, Oct. 14 to 16:—On the columella auris of the Pelycosauria, E. D. Cope; the brain of Asellus and the eyeless form of Cecidotæa, A. S. Packard; on the theory of atomic volumes, Wolcott Gibbs; on the complex inorganic acids, Wolcott Gibbs; notice of Muybridge's experiments on the motions of animals by instantaneous photography, Fairman Rogers; notice of Grant's difference-engine, Fairman Rogers; on the thinolite of Lake Lahontan, E. S. Dana; on the Mesozoic coals of the North-West, R. Pumpelly; on the work of the Northern Trans-Continental Survey, R. Pumpelly; the grasses mechanically injurious to live-stock, William H. Brewe; on gravitation survey, C. S. Peirce; on minimum differences of sensibility, C. S. Peirce and J. Jastrow; researches on Ptolemy's star-catalogue, C. H. F. Peters; on the operations of the U.S. Geological Survey, J. W. Powell; the motion of Hyperion, Asaph Hall; remarks on the civilisation of the native peoples of America, E. B. Tylor; some results of the exploration of the deep sea beneath the Gulf Stream by the U.S. Fish Commission steamer *Albatross* during the past summer, A. E. Verrill; recent progress in explosives, H. L. Abbot; on an experimental composite photograph of the members of the Academy, R. Pumpelly; report on meridian work at Carlsruhe, W. Valentiner; on the algebra of logic, C. S. Peirce.

THE meeting of the Cambridge Philosophical Society next Monday at 3 p.m. will be marked by the number and importance of the biological papers communicated. One will be by a lady, Miss F. Eves, Lecturer at Newnham College, on some experiments on the liver ferment. Mr. W. F. R. Weldon will contribute a paper on the supra-renal bodies, on which he has previously made valuable contributions. The remarkable recent development of the study of vegetable morphology and physiology under Dr. Vines will be further evidenced by Mr. Walter Gardiner's paper on the supposed presence of protoplasm in the intercellular spaces, and Mr. J. R. Green's, on a proteid occurring in plants. Prof. Michael Foster is the new President of the Society; Mr. Trotter, Mr. Glazebrook, and Dr. Vines are the Secretaries; and Prof. Cayley, Prof. Macalister, and Mr. Glaisher are the new Members of Council.

THE Statistical Society has issued in one handsome quarto a Catalogue of their most useful collection of books. The Catalogue has been compiled with great care, and on a simple and intelligible plan. The library is deemed to be a class library, and no classification therefore is attempted, the books being arranged in alphabetical order, with reference to size, under their authors' names or otherwise, as described in the preface. Secondly, their are no "*blind entries*," *i.e.* each entry, including cross-references, gives sufficient particulars, including size, to enable any person to recognise the book he is looking for, if there, and at the same time indicate to the attendant, without further reference to the Catalogue, where the book is to be found. Such features are a great comfort to the student.

MICHIGAN, like most other States, is going in for economic entomology. We have received a pamphlet of 31 pages on Injurious Insects, emanating from the Entomological Laboratory of the Michigan Agricultural College, in which Prof. A. J. Cook and Mr. Clarence M. Weed are the principal writers. Several of the usual American pests are noticed, and some are figured. We are sorry to say the figures are original, for although the practice of borrowing *clichés* has extended in the States to a degree that is almost nauseating, the results are usually satisfactory, and had the practice been followed in this instance it would have been to the advantage of this Michigan College. Probably for the first time in America the ubiquitous "Painted Lady" (*Vanessa cardui*) is stigmatised as "injurious"; it is accused of devouring hollyhock, centaurea, and borage. The same insect in Europe, a few years ago, was driven to extremes in order to find anything that would agree with it, and nearly caused a panic with the worshippers of "absinthe," by destroying the wormwood crop in the Canton of Neufchâtel (Switzerland). There are some very useful and suggestive statistics (by Mr. Weed) on the food relations of birds, frogs, and toads (the paper being a "Thesis for the degree of Master of Science"). The first part deals with the food of *young* birds, in which the American robin (a thrush, and not to be confounded with *our* redbreast) figures largely, as do also the "blue bird" and others. Lepidopterous larvæ are the main food, but apologies have to be made (especially in the case of the blue-bird) for the number of spiders destroyed. In the case of young "robins" the molluscous element is small; probably it would be equally small in this country with regard to *young* thrushes or blackbirds, their beaks not being sufficiently strong to enable them to do the shell-breaking. The statistics with regard to frogs and toads do not appear to be of importance one way or the other. Frogs and toads destroy insects (or "Arthropods" in the broad sense), but we fancy the particular food depends upon the conditions under which the individual Batrachian finds itself.

WE have much pleasure in calling attention to the issue, from the Breslau house of Eduard Trewendt, of four new numbers of that comprehensive work, the "Encyclopædia of Natural Sciences"—the 38th number of the first, and the 23rd to the 25th numbers of the second division. The 38th number of the first division brings the "Dictionary of Zoology, Anthropology, and Ethnology" as far as Gewöhnung (Habitua-

tion), and we need only refer in particular to the history of arthropology, of our knowledge of the Mollusca, Reptilia, and Amphibia, the writers of which occupy the front rank in their respective departments. The map of the "Zoological Regions," appended to Reichenow's interesting article on the "Geographical Distribution of Animals," will be much appreciated. The new numbers of the second division contain a continuation of Ladenburg's "Alphabetical Manual of Chemistry," with which might close two goodly volumes of this work. As physical chemistry has found an excellent representative in Prof. Eilhard Wiedemann, so is also industrial chemistry set forth by men of the first ability, whose contributions here will be prized by a wide circle: "Chlorine," by Prof. Heumann (with numerous woodcuts), "Chinoline," by Dr. L. Berend-Kiel, and "Cyanic Compounds," by Prof. Jacobsen. Nor must we omit mentioning the "History of Chemistry" (in No. 23), written for the "Alphabetical Manual of Chemistry" by Prof. G. Hoffmann of Kiel. The "Alphabetical Manual of Mineralogy, Geology, and Palæontology," continued with No. 24 of the second division, has now advanced to the end of the article "Krystallgestalten und Krystallographie" (Crystal Formations and Crystallography), which, along with the preceding article on "Crystals," by Prof. Kenngott, furnishes a very handsome contribution to the work in question, both articles being, moreover, very copiously illustrated. Finally, we have to announce that there will next appear a new botanical number which, among other things, will contain the beginning of a treatise on "Schleimpilze," by Dr. W. Zopf.

Some 154 prehistoric tombs near Santa Lucia by Tolmein, (Gorizia), have been lately examined by Dr. Marchesetti, the director of the Trieste Museum. Their contents were conveyed to Trieste; the excavations will be continued at the instance of the Adriatic Natural History Society, for a period of about two years. During last year Dr. Marchesetti examined another burial-ground, viz. that of Vermo, near Mitterburg (Istria), which belongs to quite another period.

Mr. T. Mellard Reade, C.E., F.G.S., in his presidential address to the Liverpool Geological Society this session, "On the Denudation of the Two Americas," showed that 150,000,000 tons of matter in solution are annually poured into the Gulf of Mexico by the River Mississippi; this, it was estimated, would reduce the time for the denudation of one foot of land over the whole basin—which time has hitherto been calculated solely from the matter in suspension—from 1 foot in 6000 years to 1 foot in 4500 years. Similar calculations were applied to the La Plata, the Amazons, and the St. Lawrence, Mr. Reade arriving at the result that an average of 100 tons per square mile per annum are removed from the whole American continent. This agrees with results he previously arrived at for Europe, from which it was inferred that the whole of the land draining into the Atlantic Ocean from America, Africa, Europe, and Asia contributes matter in solution which if reduced to rock at 2 tons to the cubic yard would equal 1 cubic mile every six years.

For several years the Director of Telegraphs at Haugesund (Norway), Herr A. Reitan, has been making experiments for the purpose of solving the problem whether fish seek places in the sea which are artificially illuminated. In order, however, to make experiments on a larger scale than hitherto, and if possible to demonstrate the value of such illuminations at great fisheries, he has received some specially-constructed electric lamps from Brussels, with which he will continue his experiments during the autumn.

The Natural History Society of Rhineland and Westphalia held their autumn meeting at Bonn. Among the papers read we note those on the forest vegetation of the extreme north-western portion of the Himalayas, by Dr. Brandis, and on the present state of the Phylloxera question in the Rhenish vineyards, by Prof. Bortkau.

At Schrems (Lower Austria) a violent shock of earthquake was felt on the night of October 8–9 at ten minutes past midnight. It was preceded by a subterranean rolling noise, lasting several minutes. The phenomenon was also observed at Zwettl and at Gmünd.

The glaciers in the Dachstein Mountains have again diminished considerably at their lower extremities. Prof. Simony has recently taken a large number of photographs of the summit of the Hohe Dachstein, of the Gosau Glacier, and the Karls ice-field, in order to execute future measurements. The surface of the lowest layers of the Karls ice-field has sunk between 2·5 and 3·2 metres since last year, and the lower end of the Gosau Glacier has receded more than twice that amount. Since about 1849 this glacier has receded more than 600 metres.

We have repeatedly referred to Hayek's "Grosser Handatlas der Naturgeschichte" (published by Moritz Perles, Vienna), which has now reached its completion.

The death is announced of Prof. Eugenio Balbi, Professor of Geography at Pavia University, a son of the celebrated geographer, Adriano Balbi. Born at Florence on February 6, 1812, he died at Pavia on October 18 last.

The Natural History Museum, established by the Committee of the International African Society at Brussels, grows in extent daily. The most recent additions are the skeletons of a chimpanzee, a gorilla, a crocodile, and a sea-cow. The Director of the Karema Station on Lake Tanganyika has forwarded a large collection of birds.

"A Norwegian" writes to point out two errors in Mr. Mattieu Williams's note on the northernmost promontory in Norway. "To call the Knivskjærodde a 'low glaciated tongue of rock' is hardly correct. The ridge is a couple of hundred feet high at least. I have before me a photograph of the cape, taken last summer by Dr. Sophus Tromholt, and which will shortly be placed before the public. The elevation is very considerable. Mr. Williams further states that there are magnificent capes abounding around the North Cape; others are above 1000 feet. This is incorrect. The highest mountain on the *coast* of Arctic Norway is the North Cape, viz. 974 feet. A belief has for many years prevailed in Norway that Knivskjærodden jutted further into the ocean than the North Cape, but it has only been *proved* this summer."

The additions to the Zoological Society's Gardens during the past week include two Rhesus Monkeys (*Macacus rhesus*) from India, presented respectively by Mr. Richard Armytage and Mrs. E. A. Russell; a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, presented by Miss N. Simonds; a Northern Mocking Bird (*Mimus polyglottus*) from North America, presented by Mr. Thomas G. Venables; a Grand Eclectus (*Eclectus roratus*) from Moluccas, presented by Miss Lawson; two Herring Gulls (*Larus argentatus*), British, presented by Mrs. Pigou; an Undulated Grass Parrakeet (*Melopsittacus undulatus*) from Australia, presented by Mr. F. Hale, F.Z.S.; a Water Rail (*Rallus aquaticus*), a Moorhen (*Gallinula chloropus*) from Norfolk, presented by Mr. T. E. Gunn; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. W. G. Brinkley; an Alligator (*Alligator mississippiensis*) from the Mississippi, presented by Mr. R. M. Middleton; a Greater White-crested Cockatoo (*Cacatua cristata*) from the Moluccas, deposited; a Black-headed Caique (*Caica melanocephala*) from Demerara, purchased; a Cape Ant Bear (*Orycteropus capensis*) from South Africa, received on approval.

OUR ASTRONOMICAL COLUMN

BARNARD'S COMET.—The following ephemeris of this comet for Greenwich midnight is deduced from the elliptical elements of Dr. Berberich, of Strasburg, which assign a revolution of $5\frac{1}{2}$ years :—

1884	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth	Sun
Nov. 6	22 5 32	101 27·8	0·0041	0·1985
8	— 10 28	100 50·3	0·0147	
10	— 15 20	100 13·3	0·0253	0·2054
12	— 20 8	99 36·8	0·0358	
14	— 24 51	99 0·7	0·0463	0·2122
16	— 29 30	98 25·2	0·0567	
18	— 34 6	97 50·1	0·0670	0·2191
20	— 38 38	97 15·5	0·0772	
22	22 43 7	96 41·4	0·0874	0·2259

The theoretical intensity of light on November 6 is 0·39, and on November 22, 0·24. As previously remarked, it is very desirable that observations of this comet for position should be continued as long as practicable, that its mean motion may be determined with sufficient precision to enable a trustworthy estimate of past planetary perturbations to be obtained. The general resemblance of the elements to those of the short-period comet of De Vico in 1844 will render such an investigation one of much interest.

THE NOVEMBER METEORS.—The earth arrives at the descending node of the first comet of 1866 on the afternoon of Thursday, November 13, and a watch may be favourably instituted on the night of that day for meteors of the stream which appears to lie in the comet's track. Oppölzer's definitive elements give for the radiant point, R.A. 150°·2, N.P.D. 67°·2 (equinox of 1866).

THE LICK OBSERVATORY, CALIFORNIA.—The following is an extract of a letter from Prof. Edward S. Holden, Director of the Washburn Observatory, University of Wisconsin, dated October 17 :—"I have just returned from the Lick Observatory, where I have mounted a beautiful meridian-circle by Repsold of 6 (French) inches aperture. It has north and south collimators of the same aperture, and its axis is a telescope of 2·5 inches aperture, which is viewed by an east (or west) collimator for controlling the azimuth, &c. There are two circles, each divided to 2′, one fixed, the other movable by a wheel and pinion, so that it is not *essential* to determine the division errors of any lines except those for each 1°, and those 2′ lines belonging to 4 degrees, 90° apart. The room is double throughout, a wooden building 40 × 40 feet inside of a structure in louvre-work, which gives a continuous air space all around ; and this air space is connected with a tall ventilating tower which enables the free circulation of air to be maintained. It appears to me to be in all respects satisfactory. The Lick Observatory now needs only its 36-inch refractor to be complete, and they hope for this within three years."

It will be remembered that this Observatory is situate on the top of Mount Hamilton.

VARIABLE STAR IN THE ORION-NEBULA.—The late Prof. Schmidt found that the star which he distinguishes as J″ (Bond 822 = Liapunov γ), which follows θ Orionis 34·3s., and 5′ 5″ to the south of it, disappeared at minimum in his 5-feet refractor, and at maximum reached 9·5m. On April 3, 1878, it was estimated 12·8, equal to Bond 784, but before the end of the month it rose to 9·7. The star may deserve frequent observation.

GEOGRAPHICAL NOTES

THE Rev. Francis A. Allen has issued a reprint of the paper read by him at the late Congress of Americanists in Copenhagen on Polynesian antiquities. The stupendous Cyclopean monuments, platforms, terraces, walls, colossal statues, scattered over the South Sea Islands are graphically described, and regarded as forming a connecting link between the ancient civilisations of Asia and America. The theory is that America was mainly peopled by two streams of migration from Asia—a nomad Mongolic, proceeding directly by the Straits of Behring, and now represented by the Apaches, Utes, Comanches, and other wild tribes of California, Oregon, Colorado, &c. ; and a semi-civilised, proceeding from Further India and China across the islands of the Pacific Ocean to Mexico, Central America, and Peru. On their way across the archipelagoes these peoples left traces of their presence in Micronesia, Hawaii, Tahiti, and especially Easter Island, the last-named distant only some 2600 miles from the mainland of South America. The resemblances between these monuments and those of Peru and Mexico are dwelt upon, and they are further compared with those of Java (Boro-Boro), Cambodia (Angkor-Vaht), and others in Southern Asia. The theory, which is not altogether novel, is supported by other arguments based on considerations of traditions, usages, religions, languages, and the like, brought together from various sources not always of a trustworthy character. It is suggested that the Chinese tradition of the discovery of Fusang by the monk Hoén-Shin may not be altogether an idle tale. Allusion is made to Schoolcraft's exploded legend of Hiawatha ; and some more than doubtful authorities are referred to in proof of the affinities between the American languages and those of Japan, North-East Siberia, and Indo-China. Nevertheless, if not always critical, the paper is learned and lucid, and worth reprinting, if only for the great number of data here brought together as bearing directly or indirectly on the point at issue.

HERR VON HAARDT contributes an instructive memoir to the last number of the *Proceedings* of the Vienna Geographical Society on the services rendered to the progress of the geographical sciences by the Austrian navy. A brief historical survey is given of the famous *Novara* Expedition round the world (1857-59) ; of the survey of the Adriatic coastlands by Capt. T. Ritter (1871) ; the simultaneous determination of the magnetic relations in the same waters by Lieut. J. Schellander ; the expedition of the *Friedrich* and *Donau* to the East Asiatic seaboard (1868) ; the second voyage of the *Donau* to Asia and South America (1874-76) ; the circumnavigation of Borneo by Capt. T. F. von Oesterreicher ; the circumnavigation of Africa by the *Helgoland* and *Friedrich* (1874-75) ; the voyages of the *Pola* to Jan Mayen and the Arctic Ocean (1882-83) ; Weyprecht's discovery of Franz-Josef Land, &c. The memoir concludes with a brief reference to the expeditions now in progress or promised in the near future, such as that of the *Saida* to Australasia (1884-86) ; of the *Aurora* to South America (1884-85) ; of the *Helgoland* to the West African seaboard, and of the *Frundsberg* to the Indian Ocean.

THE same periodical contains the first part of what promises to be a very valuable contribution to the physiography of Caucasia. Much useful information is here brought together from the latest sources regarding the orography, river systems, administrative divisions, and statistics of that region. The present area of the northern section (Cis-Caucasia) is given at 4037 German geographical square miles, of the southern (Trans-Caucasia), 4400 ; total, 8437, or 2740 more than that of the British Isles.

TO this journal F. Blumentritt also sends an account of the little-known Negrito tribes of the district of Principe in the Island of Luzon, Philippine Archipelago. These aborigines, collectively known as Atas (Aetas), and showing distinct physical resemblances to the non-Malay wild tribes of Malacca, are being gradually evangelised by the Spanish missionaries stationed at Baler. Hemmed in between the semi-civilised Tagalas and the fierce Ilongotes, both of mixed Malay stock and speech, they have already been largely affected by Malay influences. But although their language contains numerous Tagala words, expressions, and even grammatical forms, its fundamentally distinct character has been clearly determined. For the purpose of comparison useful vocabularies of about 150 words are appended in five languages: Spanish, Tagala, Negrito of Mariveles (Bataan), Negrito of Zambales, and Negrito of Baler (Principe).

AT the opening meeting of the Royal Geographical Society on Monday, Mr. Joseph Thomson gave an eloquent and highly interesting account of his recent explorations in the country of the Masai. Both the country and the people are of the greatest interest to science, and, as was shown last week, Mr. Thomson's botanical collections are decidedly novel. One or two zoological novelties he has also obtained, and we shall be glad to have the detailed account of his discoveries, which will appear in his forthcoming work.

IT appears from the *Anglo-New Zealander and Australian Times* that Mr. H. O. Forbes, F.R.G.S., is organising a scientific expedition with the view of exploring the botany and zoology of the Mount Owen Stanley Mountains, the great cen-

tral range of the eastern peninsula of New Guinea. Mr. Forbes has been allowed 400*l.* by the British Association and 250*l.* by the Royal Geographical Society towards the expense of the expedition. The party will start early in December, though it is not expected to get into active working before May next, in consequence of the necessity for procuring trusty carriers from the Moluccas. Mr. Forbes will break his journey at Batavia, in order to proceed to Amboyna, where he hopes to find his men. He will then return to Batavia, and sail for Thursday Island, proceeding thence to Port Moresby. He proposes to ascend the course of one of the rivers which flow from the mountains to Redscar Bay. Should the natives prove friendly and the food-supplies sufficient, Mr Forbes does not despair of reaching the other coast of the peninsula; but in any case the exploration of the Mount Owen Stanley Range would be of itself a satisfactory achievement. The mountain travelling is declared to be dangerous to any but very experienced travellers.

NEWS has reached St. Petersburg from Col. Prjevalsky, the indefatigable explorer in Thibet, whose expedition appears to be distinguishing itself in feats of arms as well as discoveries of science. A telegram *viâ* Kiatcha, dated August 20, says:—"The difficult task of the expedition has been successfully accomplished. During the three summer months we traversed 1000 versts of North-Eastern Thibet. We first descended from Zaidam, 400 versts south, over the sources of the Yellow River to the Blue River, which it was found impossible to cross, and then we explored the large lakes in the upper course of the Yellow River. One lake was named 'Russian,' another 'Expedition' Lake. Their height was 13,500 feet, the surrounding country being a mountain plateau 1000 feet higher. Along the Blue River lies a mountainous, but woodless and Alpine country. The climate of the localities passed through was terrible. The whole of the summer was cold, with rain and snow; at the end of May there was sharp frost, in July we had snowstorms like those of winter, while the amount of alluvium deposited by south-western monsoons from the Indian Ocean is so great that in summer Northern Thibet is converted into an almost continuous marsh. Wild animals and fish are abundant, the birds and flora poor, but original. The Tanguts live on the Blue River, and near the lakes of the Yellow River. Here we were twice attacked by about 300 mounted marauders, and the heroic conduct of my companions, armed with Berdan rifles, saved the expedition. We soon repulsed the first attack on July 25, and subsequently destroyed the Tangut camp. A week later a fresh party from another Tangut tribe attacked us. For two hours on the banks of the Yellow River we repelled the mounted brigands with repeated volleys from our rifles; and when we took the offensive the Tanguts retreated behind the knolls, and in turn began volley-firing. We were most fortunate, all coming off safe and sound, only two of our horses being wounded, while forty of the brigands were killed and wounded in the two encounters. We now go to Western Zaidam. We shall establish a depot at Hast, and during the winter explore the surrounding localities."

DR. GERHARD ROHLFS leaves for the West Coast of Africa by one of the German war-ships under Admiral Knorr, and has been intrusted with a special mission by the German Government.

CAPT. BECKER and some other Belgian officers are about to proceed to Zanzibar, thence to start for Lake Tanganyika. They intend to cross this lake, and to found a station on its western shore. Thus the line of stations across Africa, which the International African Society has planned, will be completed. On the eastern side of Lake Tanganyika, between this and the sea-coast, there are four stations: Kondoa, in Usagara; Tabora, in Unyanyembe; Kakoma, in Uganda; and Karema, on the shore of the lake. On the western side there are over fifty stations between the lake and the Atlantic.

THE subject of trade-routes into South-Western China is now engaging attention in France, and has caused much discussion in the periodical press. The various methods of reaching Szechuan and Yunnan which have from time to time been suggested by explorers are dismissed in their turn as impracticable. From the side of India we have the Brahmaputra, which is navigable almost to the Chinese frontier, and the Irrawaddy *viâ* Bahmo. These are described as useless on account of the obstacles offered by lofty and almost impassable ranges of mountains; the Meinam from Bankok would only land us in the Shan States; the Meikong, through Cambodia, was tried by Lagrée, but was found quite unfit for navigation on account of its numerous rapids and cataracts. In China we have the Sikiang—which offers an almost straight line from Canton into Southern China, and was followed by Mr. Colquhoun in his recent attempt to cross through the Shan States into British Burmah—and the Yang-tsze-kiang, but both of these routes, according to French writers, are closed to trade by Chinese hostility. Thus every possible route has been tried and found wanting, with one exception, viz. that by the Songkoi or Red River of Tonquin. By means of this new possession of France the trade of the two great provinces of South-Western China, say the French writers, can be tapped, and in no other way. Their wealth, it is said, will be poured down the valley of the Red River into the hands of the French traders at Hanoi and Haiphong. With regard to routes mentioned only to be dismissed as impossible, nothing need be said here. Their merits and defects may be found described in a score of English works by explorers on the spot; but so far as the Red River is concerned, no proposition either way can be laid down with safety. Beyond Hanoi it is but little known, and its upper waters above Honghoa are almost wholly unknown to Europeans. But one Frenchman has ever ascended or descended the river, and when M. Dupuis made his courageous journeys more than ten years ago, he did so under circumstances which rendered geographical observation impossible. All that M. Dupuis can say (and European knowledge is confined to his information) is that with an escort, and with Chinese passports, he was able to come down the river in a small junk, and to ascend it again with several junks laden with arms and ammunition. Even at the present moment the whole river from Honghoa to Laokai on the Chinese frontier is in the hands of the Black Flags. Moreover it has been stated that after leaving the Red River the route would have to cross a lofty mountain range, and pass through the most desolate region in Yunnan. The river may offer an excellent trade route; but in the present state of our geographical knowledge of Upper Tonquin all that can be said with certainty is that nobody knows whether it is so or not. Happily the French lose no time in thoroughly studying the countries which they occupy, and as soon as a state of peace has been reached in Indo-China we shall be in a position to decide the question; until then anything written about the navigation of the Red River above Honghoa is mere speculation, and valueless for practical purposes.

THE last number of the *Izvestia* of the Russian Geographical Society contains three interesting papers by M. D. Ivanoff on the Pamir, embodying the results of the last year's expedition, and giving a lively summary of our present knowledge as to this very interesting region. A. E. Regel contributes to the same number a note on his journey to the Shugnan; A. Wysheslavtseff describes the burial customs of the Tchuvashes; and P. A. Putyatin contributes a note on the pottery of the Stone Age. The same issue contains, moreover, accounts of the geodetical and cartographical work done in 1883 by the military topographers and by the Hydrographical Department, and several notes.

NATURAL SCIENCE IN SCHOOLS[1]

HOWEVER fully it may be admitted by the few that it is important, nay essential, that all members of the community, whatever their station or occupation, should during their school career receive some instruction in the elements of natural science, the general public have not as yet had brought home to them with sufficient clearness that, just as a knowledge of foreign languages is essential to all who are brought into intercourse with foreigners, so in like manner is a correct knowledge of the elements of natural science of direct practical value to all in their daily intercourse with Nature, apart from the pleasure which such knowledge affords. In fact, judged from a purely utilitarian standpoint, the advantages to be derived from even the most elementary acquaintance with what may be termed the science of daily life are so manifold that, if once understood by the public, the claims of science to a place in the ordinary school course must meet with universal recognition. To quote Huxley[2]:

[1] "On the Teaching of Natural Science as a Part of the Ordinary School Course, and on the Method of Teaching Chemistry in the Introductory Course in Science Classes, Schools and Colleges." Paper read at the Educational Conference of the International Health Exhibition by Henry E. Armstrong, Ph.D., F.R.S., Sec.C.S., Professor of Chemistry in the Finsbury Technical College.

[2] This writer's "Introductory" to Macmillan's Science Primers, and his "Physiography: an Introduction to the Study of Nature," should be studied by all who wish to know what science is and how it should be taught.

"Knowledge of Nature is the guide of practical conduct; . . . any one who tries to live upon the face of this earth without attention to the laws of Nature will live there for but a very short time, most of which will be passed in exceeding discomfort: a peculiarity of natural laws, as distinguished from those of human enactment, being that they take effect without summons or prosecution. In fact, nobody could live for half a day unless he attended to some of the laws of Nature; and thousands of us are dying daily, or living miserably, because men have not yet been sufficiently zealous to learn the code of Nature."

But it is also and mainly on other and far higher grounds that we should advocate universal practical teaching of the elements of natural, and more particularly of so-called physical, science: viz. that it tends to develop a side of the human intellect which. I believe I am justified in saying, is left uncultivated even after the most careful mathematical and literary training: the faculty of observing and of reasoning from observation and experiment. It is entirely from this latter point of view that I shall venture to propound a scheme for teaching the elements of that branch of physical science with which I am most intimately acquainted.

This Exhibition affords some few noteworthy illustrations of the way in which the importance of teaching the elements of natural science has received practical recognition in our schools. Thus we have indications of the work being done by the Birmingham School Board; the London School Board call attention to their system of training pupil-teachers in science; Mr. Robins shows plans of one of the best, if not the best equipped school chemical laboratory—that of the Manchester Grammar School. Also, it is well known that at many of the larger schools, such as Clifton College, Eton, Harrow, Rugby, St. Paul's, Giggleswick, and the North London Collegiate School for Girls, ample provision is made for teaching one or more branches of natural science; and not a few other examples might be quoted. But in how large a proportion of the schools throughout the country is such training neglected? and there is much cause for complaint in the fact that, in those schools in which science is taught, it is after all in most cases but a kind of "refuge for the destitute," only those who have failed on the classical side and those judged to be inferior in intellect being turned over to the so-called modern side. This is probably due to a variety of causes: to the ignorance already referred to of the public of the importance and value of such training, or it would be demanded of the schools; to the ignorance of even the barest elements of science of the majority of teachers in charge of schools; to the want of good science teachers and of suitable books; to the supposed expense of teaching science; and lastly—and I believe this to be the most important of all the causes which operate against the teaching of science—to the imperfection of our method of teaching: there can be little doubt, in fact, that the majority of teachers of the generally recognised subjects who have themselves no scientific knowledge see clearly enough that very little good comes of teaching science in the manner in which it is commonly taught in schools.

The great objection to the method at present in vogue appears to me to be that it is practically the same whether science is taught as a part of the general school course, or whether it is taught professionally; in other words, a lad studies chemistry, for example, at school in just the same way as at a science college, the only difference being that he does not carry his studies so far at school as at college. This, I believe, is the primary fault in our present system. In my opinion, no single branch of natural science should be selected to be taught as part of the ordinary school course, but the instruction should comprise the elements of what I have already spoken of as the science of daily life, and should include astronomy, botany, chemistry, geology, mechanics, physics, physiology and zoology—the *olla podrida* comprehended by Huxley under physiography, but which is perhaps more happily expressed in the German word *Naturkunde*—in so far as is essential to the understanding of the ordinary operations and objects of Nature, the teaching from beginning to end being of as practical a character as possible, and of such a kind as to cultivate the intelligence and develop the faculties of observing, comparing and reasoning from observation; and the more technical the course the better. The order in which these subjects should be introduced is matter for discussion; personally, I should prefer to begin with botany, and to introduce as soon as possible the various branches of science in no particular order but that best suited to the understanding of the various objects or phenomena to which the teaching for the time being had reference. The extent to which instruction of this kind is given must entirely depend on the class of scholars.

There are few teachers capable of giving such instruction, and fewer books of a character suited to ordinary requirements. The development of such a system will, in fact, require the earnest co-operation of a number of specialists; but apart from the difficulty of securing efficient co-operation, there is no reason why some such scheme should not be elaborated at no distant date. If action is to be taken, however, there must be no delay, or the opportunity will be lost. I trust that this meeting will be prepared to give much attention to this question, and that it may be possible to continue the discussion on other platforms, as it is fundamentally important and deserving of the most serious consideration of educationalists. No doubt it will be said that the object of introducing the teaching of science into the school course is to afford mental training of a particular character, not the inculcation of useful knowledge, and that this end can be secured by teaching well some one branch of science. Admitting that this has been the case, however, there is no reason why it should be in the future: if while developing the intellect it be possible—and it certainly is—to impart much valuable information; and if—as it certainly is—the teaching be rendered easier and more attractive because it has direct reference to the familiar objects and operations of Nature. We cannot, indeed, any longer afford to grow up ignorant of all that is going on around us, and without learning to use our eyes and our reasoning powers; we cannot afford to be unacquainted with the fundamental laws of health; but we must ever remember "that knowledge of Nature is the guide of practical conduct," and no effort must be spared to render our system of education an effectual preparation and truly adapted to the exigencies of practical life. The female educators appear already to have grasped the importance of such teaching, and under the guise of domestic economy much that I advocate is being taught in girls' schools; it is to be hoped that ere long something akin to the domestic economy course in girls' schools will find a place in boys' schools.

To pass now to the consideration of the mode of teaching my own special subject in science classes, such as those held under the auspices of the Science and Art Department, and in the introductory course for students in science schools and colleges generally. To deal first with the former. Inspection of the syllabus for the elementary stage, together with the study of the examination papers of the past few years, will show that the student is mainly required to have an elementary knowledge of the methods of preparing, and of the properties of, the commoner *non-metallic* elements and their chief compounds. There is thus practically no distinction to be drawn between the knowledge required of students under the Science and Art Department, and of those who are making the study of chemistry the business of their lives. But surely it is not the function of the Science and Art Department to train up chemists, and I am satisfied that it is neither their desire nor their intention to do so; their object undoubtedly is to encourage the teaching of chemistry as a means of cultivating certain faculties, and in order that the fundamental laws of chemistry may be understood and their commoner applications realised. It is not difficult to understand how the system has grown up and why it is maintained; I not believe it is because the Department consider it a satisfactory one; but they know full well that a better system is not yet developed, and that it would be unwise to legislate far in advance of the intelligence and powers of the majority of the teachers. With all deference, however, I venture to add that the programme has been drawn up too much from the point of view of the specialist, and that too little attention has been devoted to it from the point of view of the educationalist. The course I am inclined to advocate would be of a more directly useful character. There is no reason why in the beginning attention should be confined to the non-metals, especially when certain of the metals enter so largely into daily use; and provided that it involve no sacrifice of the opportunities of developing the faculties which it is our special object to cultivate by the study of chemistry, there is no reason against, but every reason for, selecting subjects of every-day importance rather than such as are altogether outside our ordinary experience, such, for example, as the oxides of nitrogen: even chlorine, except in relation to common salt, might be omitted from special study. The presumed distinction between so-called inorganic and organic chemistry should be altogether put aside and forgotten, and the elements of the chemistry of the carbon compounds introduced at a very early stage in order that the phenomena of animal and plant life might come under consideration. To give the barest possible outline of a programme, I would include such subjects as the following in the syllabus:—

The chemistry of air, of water, and of combustion; the

distinction between elements and compounds; the fundamental laws which regulate the formation of compounds and the chemical action of bodies upon one another (*i.e.* the nature of so-called chemical change); the chemical properties of the metals in ordinary use, with special reference to their uses and the action upon them of air, water, &c.; the composition of natural waters; the distinction between fats, carbohydrates and albuminous substances in so far as is essential to the understanding of the relative values of different foods and respiration and growth in animals and plants (outlines of the chemistry of animal and plant life, in fact); the nature of the processes of fermentation, putrefaction, and decay.

The instruction in these subjects should in all cases be imparted by means of object-lessons and tutorial classes; lectures pure and simple should, as far as possible, be avoided. The students should by themselves go through a number of practical exercises on the various subjects. I would abolish the teaching of tables for the detection of simple salts, the teaching of analysis as at present conducted being, I believe, in most cases of very little if any use except as enabling teachers to earn grants.

In schools and colleges in which chemistry is taught as a science, and ostensibly with the object of training young people to be chemists, it is the almost invariable practice that the student first devotes more or less time to the preparation of the commoner gases, and then proceeds to study qualitative analysis; quantitative determinations are made only during the later period of the course. I believe that the system has two great faults: it is too mechanical, and does not sufficiently develop the faculty of reasoning from observation; and actual practice in measurement is introduced far too late in the course. It is of great importance that the meaning of the terms equivalent, atomic weight, molecular weight, should be thoroughly grasped at an early stage, but according to my experience this is very rarely the case; there is no such difficulty, however, if the beginner is taught to make a few determinations himself of equivalents, &c., as he very well may be. It is not necessary here to enter into a more detailed criticism, but I propose instead to give a brief description of a modification of the existing system which in my hands, in the course of about four years' experience, has furnished most encouraging results, and which I venture to think is worthy of an extended trial.

Instead of merely preparing a variety of gases, the student is required to solve a number of problems experimentally: to determine, for example, the composition of air and of water; and the idea of measurement is introduced from the very beginning, as the determination is made quantitatively as well as qualitatively. Each student receives a paper of instructions—two of which are printed as an appendix to this paper—which are advisedly made as bare as possible so as to lead him to find out for himself, or inquire, how to set to work; and he is particularly directed that, having made an experiment, he is to enter in his notebook an account of what he has done and of the result, and that he is then and there to ask himself what bearing the result has upon the particular problem under consideration, and, having done so, he is to write down his conclusion. He is thus at once led to consider what each experiment teaches: in other words, to reason from observation. Apart from the mental exercise which this system affords, if the writing out of the notes be properly supervised, the literary exercise which it also affords is of no mean value.

In illustration, I may here very briefly describe the manner of working out the second problem in the course. The problem being to determine the composition of water, the student receives the instruction:—1. Pass steam over red-hot iron brads, collect the escaping gas, and apply a light to it. (N.B. The gas thus produced is called hydrogen.) He is provided with a very simple apparatus, consisting of a small glass flask containing water, joined by a narrow bent glass tube to an iron tube (about 9 inches long and $\frac{1}{2}$ to $\frac{3}{4}$ inch wide) in which the brads are placed, a long glass tube suitably bent for the delivery of the gas being attached to the other end of the iron tube. Plaster of Paris is used instead of corks to make the connections with the iron tube. The iron tube is supported over a burner, and heated to redness; the water in the flask is then heated to boiling, and the steam thus generated is passed over the brads; the escaping gas is collected over water in the usual manner. Having made this experiment, and observed that, on passing steam over red-hot iron, the gas hydrogen is produced, the student proceeds to consider the bearing of this observation. The hydrogen must obviously be derived either from the water or from the iron, if not from both. Those who already know that iron is iron, so to speak, at once infer that the hydrogen is derived from the water: it is, however, pointed out that, even if it be known that iron is a simple substance, this observation taken alone does not prove that hydrogen is contained in water.

2. The student next learns to prepare hydrogen by the ordinary method of dissolving zinc in diluted sulphuric acid, and makes a few simple experiments whereby he becomes acquainted with the chief properties of the gas.

3. Having done this, he is instructed "to burn dry hydrogen at a glass jet underneath a cold surface and to collect and examine the product." The product is easily recognised as water, and the immediate answer to the question, "What does this observation teach?" is, that since iron is absent, taken in conjunction with Experiment 1, the production of water on burning hydrogen in air, the composition of which has already been determined, is an absolute demonstration that hydrogen is contained in water.

4. Having previously studied the combustion of copper, iron, and phosphorus in air, and having learnt that when these substances burn they enter into combination with the oxygen in air, the student is also led to infer from the observation that hydrogen burns in air producing water, that most probably it combines with the oxygen, and that water contains oxygen besides hydrogen. It may be however, it is then pointed out, that the hydrogen, unlike the phosphorus, &c., combines with the nitrogen instead of with the oxygen, or perhaps with both. He is therefore instructed to pass oxygen over heated copper, weighing the tube before and after the operation, and subsequently to heat the "oxide of copper" in a current of hydrogen. He then observes that water is formed, the oxygen being removed from the copper: and since nitrogen is absent, it follows that water consists of hydrogen and oxygen, and of these alone.

5. By repeating this last experiment so as to ascertain the loss in weight of the copper oxide tube and the weight of water produced, the data are obtained for calculating the proportions in which hydrogen and oxygen are associated in water.

In practice the only serious difficulty met with has been to induce students to give themselves the trouble to consider what information is gained from a particular observation; to be properly inquisitive, in fact. I cannot think that this arises, as a rule, from mental incapacity. When we consider how the child is always putting questions, and that nothing is more beautifully characteristic of young children than the desire to know the why and wherefore of everything they see, I fear there can be little doubt that it is one of the main results—and it is indeed a lamentable result—of our present school system that the natural spirit of inquiry, inherent to a greater or less extent in every member of the community, should be thus stunted in its growth, instead of being carefully developed and properly directed.

Having in the manner which I have described studied air, water, the gas given off on heating common salt with sulphuric acid, and the ordinary phenomena of combustion, the student next receives a paper with directions for the comparative study of lead and silver (see Appendix). The experiments are chosen so as to afford an insight into the principles of the methods ordinarily employed in qualitative and quantitative analyses, and the student who has conscientiously performed all the exercises is in a position to specialise his studies in whatever direction may be desirable.

The system I have thus advocated undoubtedly involves far more trouble to the teacher than that ordinarily followed, but the student learns far more under it, and I assert with confidence that the training is of a far higher order, and also of a more directly useful character. I believe it to be generally applicable, and that it would be of special advantage in those cases in which only a short time can be devoted to the study of chemistry, as in evening classes and medical schools. At present the only practical teaching vouchsafed to the majority of students in our large medical schools is a short summer course, during which they are taught the use of certain analytical tables: as a mental exercise the training they receive is of doubtful value; the knowledge gained is of little use in after life, and the course certainly ought not to be dignified by being spoken of as a course of Practical Chemistry; *test-tubing* is the proper appellation. It is not a little remarkable also that even the London University Syllabus nowhere specifies that a knowledge even of the elements of quantitative analysis will be required of candidates either at the Preliminary Scientific or First M.B. Examination, and this, too, when, as is well known, an analysis to be of any practical

value must almost invariably be quantitative. It is little less than a disgrace to the medical profession that a subject of such vital importance as chemistry should be so neglected.

If, however, we are to make any change in our method of teaching science, if we are to teach science usefully throughout the country, two things are necessary: teachers of science must take counsel together, and the examining boards must seriously consider their position. There can be little doubt that in too many cases the examinations are suited to professional instead of to educational requirements; and that the professional examinations are often of too general a character, and do not sufficiently take into account special requirements.

APPENDIX

Problem: to Determine the Composition of Air

N.B.—Immediately after performing each experiment indicated in this and subsequent papers, write down a careful description of the manner in which the experiment has been done, of your observations and the result or results obtained, and of the bearing of your observations and the result or results obtained on the problem which you are engaged in solving. Be especially on your guard against drawing conclusions which are not justified by the result of the experiment; but, on the other hand, endeavour to extract as much information as possible from the experiment.

1. Burn a piece of *dry* phosphorus in a confined volume of air, *i.e.* in a stout Florence flask closed by a caoutchouc stopper. Afterwards withdraw the stopper under water, again insert it when water ceases to enter and measure the amount of water sucked in. Afterwards determine the capacity of the flask by filling it with water and measuring this water.

N.B.—The first part of the experiment requires care and must be done under direction.

2. Allow a stick of phosphorus lashed to a piece of stout wire to remain for some hours in contact with a known volume of air confined over water in a graduated cylinder. After noting the volume of the residual gas, introduce a burning taper or wooden splinter into it.

N.B.—The residual gas is called *nitrogen*.

3. Burn a piece of dry phosphorus in a current of air in a tube loosely packed with asbestos. Weigh the tube, &c., before and after the experiment.

4. Repeat Experiment 2 with iron borings moistened with ammonium chloride solution. Preserve the residual gas.

5. Suspend a magnet from one arm of a balance; having dipped it into finely divided iron, place weights in the opposite pan, and when the balance is in equilibrium, set fire to the iron.

6. Pass a current of dry air through a moderately heated tube containing copper. Weigh the tube before and after the experiment; also note the alteration in the appearance of the copper.

7. Strongly heat in a *dry* test tube the red substance obtained by heating mercury in contact with air. At intervals plunge a glowing splinter of wood into the tube. Afterwards note the appearance of the sides of the tube. (Before performing this experiment ask for directions.)

N.B.—The gas obtained in this experiment is named *oxygen*.

8. Heat a mixture of manganese dioxide and potassium chlorate in a dry test tube, and at intervals plunge a glowing splinter into the tube. This experiment is to acquaint you with an easy method of preparing oxygen in quantity.

9. Prepare oxygen as in Experiment 8, and add it to the nitrogen from Experiment 4 in sufficient quantity to make up the bulk to that of the air taken for the latter experiment. Test the mixture with a burning taper or splinter.

10. Dissolve copper in nitric acid and collect the escaping gas (nitric oxide); add some of it to oxygen and some of it to air.

11. Fill a large flask provided with a well-fitting caoutchouc stopper and delivery tube with ordinary tap water and gradually heat the water to the boiling-point; collect the gas which is given off in a small cylinder and add nitric oxide to it. Also collect a sufficient quantity in a narrow graduated cylinder and treat it as in Experiment 2.

Comparative Study of Silver and Lead

Silver.—*Symbol*, Ag. (*Argentum*). *Atomic weight*, 107·67. *Specific heat*, ·05701.

Lead.—*Symbol*, Pb. (*Plumbum*). *Atomic weight*, 206·47. *Specific heat*, ·03140.

1. Determine the relative density of lead and silver at a known temperature by weighing in air and in water.

2. Separately heat known weights of lead and silver for some time in the air, allow to cool, and weigh.

3. Separately convert known weights of lead and silver into nitrates, and weigh the latter. From the data thus obtained calculate the *equivalents* of lead and silver.

4. Convert the known weights of nitrates thus obtained into chlorides, and weigh the latter.

5. Compare the action on lead and silver of chlorhydric acid; of dilute and concentrated sulphuric acid, using the acid both cold and hot; and of cold and hot nitric acid.

6. Using solutions of the nitrates, compare their behaviour with chlorhydric and sulphuric acids, hydrogen sulphide, potassium iodide, and potassium chromate. Ascertain the behaviour of the precipitate formed by chlorhydric acid when boiled with water, and when treated with ammonia solution.

7. Compare the behaviour of lead and silver compounds on charcoal before the blowpipe.

8. Tabulate the results of your experiments with lead and silver in parallel columns.

9. Ascertain whether the substances given you contain lead or silver.

10. Determine silver in an alloy of lead and silver by cupellation.

11. Study the method of determining silver volumetrically by means of a *standard solution* of ammonium thiocyanate. Determine the percentage of silver in English silver coinage.

12. Determine silver as chloride by precipitation.

13. Dissolve a known weight of lead in nitric acid, precipitate it as sulphate, collect and weigh the latter.

14. What are the chief ores of lead and silver? How are lead and silver extracted from their ores? How is silver separated from lead? How is it separated from burnt Spanish pyrites? What are the chief properties and uses of lead and of silver? State the composition of the chief alloys of lead and silver.

TRANSACTIONS OF THE NEW ZEALAND INSTITUTE

VOLUME XVI. of the *Transactions and Proceedings of the New Zealand Institute* contains the more important memoirs laid before its eight incorporated Societies during the year 1883 and the first weeks of 1884. It forms a bulky volume of about 650 pages, and is illustrated by 44 plates. It speaks a great deal for the energy of the able editor, Dr. James Hector, F.R.S., that he has in so short a time reduced such a mass of material into order, and that the volume should be issued in May of this year. While we think the illustrations still leave something to be desired as to their general style and execution, this volume is extremely creditable to the colony, and the amount of accurate research recorded will, if continued, soon make New Zealand one of the most completely investigated regions of the world. Of the 57 articles selected from the papers read before the local Societies, 25 relate to zoology, 22 to botany, 5 to geology, 1 to chemistry, and 4 to miscellaneous subjects. While of the titles of these papers we append a classified list, some few of them merit a more particular reference.

Mr. E. Meyrick contributes a third series of his descriptions of New Zealand Microlepidoptera, treating this time of the Œcophoridæ. This is the principal family of the Tineina in New Zealand, as is also the case in Australia. Some 67 species are recorded, of which 55 are particularly described, but the total number of species it is thought will be much more considerable. In New Zealand the family constitutes about a sixth of the entire Microlepidoptera, in Australia it forms more than a fourth, whilst in Europe it is about a thirtieth. It seems strange that, while this family occupies so prominent a position in both New Zealand and Australia, no species as far as is yet known is common to both. Fourteen genera are found in New Zealand; of these ten are endemic, three occur also in Australia, and one is cosmopolitan. Of the three genera shared with Australia, two (Eulechria and Phlæopola) are large and typically Australian genera, represented in New Zealand by three species, obviously mere stragglers; the third (Trachypepla) is a typical New Zealand genus, probably of considerable extent, and is represented in Australia by two species only, evidently also stray wanderers. Of the ten endemic genera, none are very closely related to Australian forms. It would therefore appear that, while it is not improbable that a slight interchange of species has taken place at some not exceedingly remote period, it seems nearly certain that the group is of

much more ancient origin, and was derived from another and quite distinct region. Incidentally Mr. Meyrick suggests an affinity with South America, but in a collection made by the Rev. T. Blackburn in the Hawaiian Islands, the Œcophoridæ appeared to be altogether absent, their place being taken by a peculiar group of Gelechidæ.

Mr. Meyrick also contributes a monograph of the New Zealand Geometrina. He does this with some diffidence, owing to the difficulties he has laboured under of consulting type specimens and of the absence of works of reference. A large number of published names are reduced to the rank of synonyms; some 30 species are added to the list, which now stands at 89. In addition to the description of both genera and species, analytical tables of these are given throughout, and the monograph appears to be such as will enable the student to easily identify his captures and will still induce him to the further study of this group, and especially to the transformations of the species contained in it.

Capt. F. W. Hutton gives a very important revised list of the land Mollusca of New Zealand. From the ample collections that have passed under his examination, he has been enabled to determine satisfactorily all but a very few of the described species, as well as to indicate fairly their distribution in the islands. The list contains 116 species, of which 13 remain unknown to the author. Seven have been introduced from England. The dentition of 60 and the internal anatomy of 26 species have been described by Capt. Hutton in vols. xiv. and xv. of the *Transactions*. So far as at present known, one-half of the species are confined to the North Island, one-quarter to the South Island, and one-quarter are common to both. The closest connection of the land molluscan fauna would appear to be with North Australia, but there is a considerable generic affinity with the faunas of New Caledonia, Polynesia, and South America.

An interesting paper on the habits of earthworms in New Zealand is contributed by Mr. A. T. Urquhart. The species are not named, but with such wonderful opportunities as Mr. Urquhart possesses for making a collection of these, may we hope that, in addition to his following out his painstaking observations as to their habits, he will also advance science by making a careful collection of the forms and placing them in the hands of some of the able naturalists of the Auckland Institute for description? It will be remembered that Darwin assumes that in old pastures there may be 26,886 worms per acre, and that Henson gives 53,767 worms per acre for garden ground and about half that number in corn-fields. Mr. Urquhart gives, as the result of his investigations of an acre of pasture-land near Auckland, the large number of 348,480 worms as found therein. It being suggested to him that in his selection of the spots for examination he may have unconsciously selected the richest, the experiment was again tried in a field seventeen years in grass. A piece was laid out into squares of 120 feet, and a square foot of soil was taken out at each corner; worms hanging to the side walls of the holes were not counted, and in one hole, where the return of worms was a blank, the walls were crowded with worms. As a result there was an average of 18 worms per square foot, or 784,080 per acre. Although this average is very striking when compared with that of Henson, it is worthy of note that the difference between the actual weight of the worms is not so marked. According to Henson, his average of 53,767 worms would weigh 356 pounds, while Mr. Urquhart finds that the average weight of the number found by him came to 612 pounds 9 ounces.

Apropos of a description of the head in *Palinurus lalandii*, by Prof. T. Jeffery Parker, founded on specimens which happened to be brought on board at the Cape of Good Hope during his voyage to New Zealand, we have a very natural classification of the species of this genus offered to us. The genus Palinurus, Fabr., would contain three subgenera. For the species in which the stridulating organ is absent and the procephalic processes are present Prof. Parker proposes the very appropriate generic name of Jasus; while for those forms in which the stridulating organ is present and the procephalic processes are absent he would reserve the name Palinurus, Fabr., retaining Gray's subgenus Panulirus for the longicorn species. He notes that, omitting *P. longimanus* and *P. frontalis*, of which he could obtain no definite information, all the species of Jasus are confined to the Southern Hemisphere (Ethiopian and Australian Regions); and those of Palinurus are restricted to the Northern Hemisphere; while those of Panulirus occur in both Hemispheres.

Dr. Walter Buller furnishes a series of notes on some rare species of New Zealand birds. *Sceloglaux albifacies*, the laughing owl, has been found by Mr. W. W. Smith in deep fissures of the limestone rocks at Albury, near Timaru. After many futile efforts Mr. Smith bethought himself of smoking them out; after a few whiffs the owls began sniffing, and then in a few moments quietly walked out; four were captured. They soon became quite tame. On waking up at nightfall, their call was "precisely the same as two men cooeying to each other from a distance." The male is the larger and stronger bird, with a harsher cry. The female performs most of the duty of hatching. They showed a decided perference for young rats, but would eat beetles, lizards, mice, or mutton. The crannies of the rocks in which they make their nests and live during the day are dry, very narrow at their entrance, and often five or six yards in depth. While casting their feathers they become almost naked, and two of Mr. Smith's birds while in this state were stung to death by a swarm of bees which passed through the wire netting of their cage.

Mr. R. H. Govett gives some startling facts as to the bird-killing powers of *Pisonia brunoniana* or *P. sinclairii*. A sticky gum is secreted by the carpels when they attain their full size, but is nearly as plentiful in their unripe as in their ripe condition. Possibly attracted by the flies which embalm themselves in these sticky seed-vessels, birds alight on the branches, and on one occasion two Silver-eyes (Zosterops) and an English sparrow were found with their wings so glued that they were unable to flutter. Mr. Govett's sister, thinking to do a merciful act, collected all the fruit-bearing branches that were within reach, and threw them on a dust-heap. Next day about a dozen silver-eyes were found glued to them, four or five of the pods to each bird. She writes:—"Looking at the tree one sees tufts of feathers and legs where the birds have died, and I don't think the birds could possibly get away without help. The black cat just lives under the tree, a good many of the birds falling to her share, but a good many pods get into her fur, and she has to come and get them dragged out." In a note Mr. T. Kirk says that *Pisonia umbellifera*, Seeman, = *P. sinclairii*, Hook. f., is found in several localities north of Whangerei, both on the east and west coasts, also on the Taranga Islands, Arid Island, Little Barrier Island, and on the East Cape, possibly in the last locality planted by the Maoris. The fruiting pericarp is remarkable for its viscidity, which is usually retained for a considerable period after the fruit is fully matured. It can be readily imagined that small birds tempted to feed on the seeds might easily become glued to a cluster of fruits.

Among new species of plants collected on Stewart Island by Mr. Kirk, he describes a beautiful new Olearia (*O. traillii*), called after his old and valued friend C. Traill, who has done so much for the natural history of Stewart Island. It forms a large shrub from five to twelve feet high. The terminal panicles are from four to nine inches long. The disk florets are purple. It is one of the most striking plants in the New Zealand flora, and one we hope we may soon see in cultivation. Mr. Kirk also, among other important contributions, publishes notes on Carmichaelia with descriptions of new species, one of which, *C. uniflora*, seems to be the same as a new species, with the same specific name, described in a paper read the same night before the Wellington Philosophical Society by Mr. J. Buchanan.

Mr. J. Buchanan gives an interesting account of Campbell Island and its flora. The island, thirty miles in circumference, is three good days' steaming from Wellington. Peat abounds, and the soil is extremely damp in the low-lying regions. The highest altitude is 1500 feet. Only a day and two half-days were available for botanical research, but five species were added to the flora, of which three were new. Many of the species had large and showy flowers, such as *Celmisia vernicosa*, Hook. f., and the various species of Pleurophyllum. These and the like were confined within an altitudinal range of 500 feet above sea-level, but the shrubby forms, such as species of Coprosma, Drachophyllum, Veronica, and Myrsine, ranged from sea-level, where they were most abundant, to the highest altitude. An Alpine flora may also be recognised, as a few plants were only found at the highest altitude, such as *Gentiana concinna*, Hook. f., and *Trineuron spathulata*, Hook. f.

Mr. T. F. Cheeseman contributes a very valuable revision of the New Zealand species of Carex, admitting 40 species, of which 25 are peculiar to the country; of the other fifteen found elsewhere, eleven are recorded from Tasmania and Australia, nine of these are found in Europe, North and West Asia, and North America, seven in Southern or Eastern Asia, six

in temperate North and South Africa, and four or five come from extra-tropical South America.

We can only direct general attention to Mr. Justice Gillies' important paper giving the result of his experiments in 1882-83 on the production of sugar from Sorghum, which seem to have been most successful, and to give promise of a good future for sugar-making in the colony; and to Mr. W. Arthur's report on the brown trout introduced into Otago.

Zoology.—E. Meyrick, New Zealand Microlepidoptera and Geometrina; R. W. Fereday, new species of Cidaria; T. H. Potts, on a species of Mantis; W. M. Maskell, on new Coccidæ; Geo. M. Thomson, new Crustacea and Pycnogonida; C. Chilton, New Zealand sessile-eyed Crustacea; T. Jeffery Parker, on Palinurus; A. T. Urquhart, habits of earthworms; Capt. F. W. Hutton, revision of land Mollusca, of recent Rhachiglossate Mollusca, new species of Mollusca; H. B. Kirk, Anatomy of *Sepioteuthis bilineata*; Dr. J. von Haast, occurrence of the Red Phalarope in New Zealand; Dr. W. Buller, notes on rare birds; Prof. T. J. Parker, on the occurrence of some rare fishes; Dr. Hector, notes on New Zealand ichthyology.

Botany.—W. Colenso, further contributions to New Zealand botany; J. D. Enys and T. Kirk, *Botrychium lunaria* in New Zealand; T. Kirk, botanical notes, descriptions of new species of plants; J. Adams, the botany of the Thames goldfields; A. T. Urquhart, the spread of the Eucalyptus; J. Buchanan, notes of new and rare plants, Campbell Island and its flora; Charles Knight, Lichenographia of New Zealand; T. F. Cheeseman, additions to New Zealand flora, revision of the genus Carex (New Zealand species).

Chemistry.—J. A. Pond, the pottery clays of Auckland district.

Geology.—R. M. Laing, thermal springs at Lyttelton; H. Cox, new minerals; Captain F. W. Hutton, the lower gorge of the Waimakariri; D. Sutherland, discoveries near Milford Sound.

Miscellaneous.—W. Arthur, brown trout introduced into Otago; Mr. Justice Gillies, Sorghum experiments, 1882-83; Coleman Phillips, the law of gavelkind, a reply to Messrs. George and Wallace.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 27.—M. Rolland, President, in the chair.—Remarks on the first volume of the late M. Dumas' "Discours et Éloges Académiques," presented to the Academy by M. J. Bertrand.—Note on contaminated waters in connection with the spread of cholera, by M. Marey. A careful study of this epidemic since its first appearance in Europe, together with some personal observations in Paris and other parts of France, have convinced the author that the disorder is propagated chiefly through the medium of water. All other influences are of secondary importance, so that to secure the purity of drinking-water in every affected locality should be the first care of the sanitary authorities.—On the formation of saltpetre in plants, by MM. Berthelot and André.—On the oxidation of copper, by MM. Debray and Joannis.—On the laws determining the penetration of the rolled plates of ironclads by projectiles, by M. Martin de Brettes.—On the employment of the aqueous solution of the sulphuret of carbon for the destruction of Phylloxera, by M. A. Rommier.—Account of an easy process for rapidly preparing solutions containing sulphuret of carbon in large quantities, by M. Ach. Livache.—Observations of the lunar eclipse of October 4, made at the Observatory of Lyons (Brunner 6-inch equatorial), by M. Gonnessiat.—Observations of the comets of Barnard and of Wolf made at the Observatory of Lyons (Brunner 6-inch equatorial), by M. Gonnessiat.—On a representation of the exponential function by an infinite product, by M. R. Lipschitz.—On the equilibrium of a homogeneous segment of a revolving paraboloid floating on a fluid, by M. Em. Barbier.—Measure of the horizontal component of terrestrial magnetism by the method of amortisement, by M. J. B. Baille.—Note on the relation between temperatures and pressures of the protoxide of liquid carbon, by M. V. Olszewski.—On some reactions of chlorochromic acid, by M. Quantin. The oxide of carbon acting alone on chlorochromic acid changes it to a green sesquioxide of chromium and to a violet sesquichloride. The simultaneous action of the oxide of carbon and of an excess of chlorine changes integrally the oxychloride of chromium to a sesquichloride.—Chemical analysis of the apatite (phosphate of calcium) occurring at Logrozan in Spain, by M. A. Vivier.—On a graphic granite with large crystals of chlorophyllite from the banks of the Vizézy near Montbrison (Loire), by M. F. Gonnard.—Heat of combination of the compounds of hydrogen and oxygen, by M. A. Boillot.—On the phenomena accompanying the solar corona at present visible in the Alps, by M. Duclaux. These phenomena are regarded as purely atmospheric, the sun being merely the luminous source. The solar corona itself is attributed to normal although rare causes, and is considered as analogous to the halo so often observed round the moon, when the atmosphere is charged with moisture.—Observation of the solar coronas during the aërostatic ascents of October 23 and 24, by MM. A. and G. Tissandier.—Note on solar energy and the oscillations of the magnetic needle, by M. Duponchel. From the observations made from the middle of the sixteenth century down to the present time the author infers that the secular variations of the needle are due to the action of a new ultra-Neptunian planet which he names the *Ocean*, and which may have a revolution of about 467 years. This planet must have passed through the longitudes 80° and 260° about the years 1580 and 1813, and should now be in the longitude of 314° in the constellation of Capricorn.—Note on the employment of hydrosulphuric acid for discharging colours, by M. A. Gérardin. This acid, discovered by M. Schützenberger, and now extensively employed, produces remarkable effects, acting by reduction, contrary to chlorine and oxygen, which act by oxidation. This property seems capable of important industrial application.—Note on distilled water used for drinking-purposes, by M. A. Hureau de Villeneuve. The author argues that the price of distilled water might be greatly reduced by obtaining it from steam-engines at work in mills; that it is neither unpalatable nor difficult to digest; that it generally contains a sufficient quantity of air, and that the absence of calcareous salts is rather an advantage than a drawback.

WORLD-LIFE

World-Life; or, Comparative Geology. By Alex. Winchell, Professor of Geology in the University of Michigan. Pp. 642. (Chicago: Griggs, 1883.)

AT the present day cyclopædic knowledge has become very rare, and a scientific man is generally like a miner intent on his own special shaft, and too often careless or ignorant of the general plan of the whole mine of science. The work of the collator and summariser is thus continually rising in importance, and care, patience, and judgment are now more requisite than ever before. Although these scientific "consolidation acts" can hardly fail to be open to criticism, yet every man of science must receive them with gratitude, for they afford him a general view of his science, and furnish him with a useful repertory of reference.

In this work Prof. Winchell's field is very wide, when he undertakes to collate astronomy, cosmogony, and geology, in the widest acceptation of these terms. So many subjects does this book touch on that it will only be possible within the limits of an article to give a general view of its scope. The author's reading has been extensive, and we are glad to observe that copious references are provided. He expounds with care, although perhaps sometimes too diffusely, the views of many writers, and thus brings to a focus a great mass of literature, and his own speculations are generally interesting, although not always above criticism.

As already indicated, this work is intended to give a general survey of stellar and planetary systems, to note the marks of evolutionary processes revealed by the telescope, to discuss various cosmogonic theories, to examine the probable life-histories of nebulæ, suns, planets, and satellites, and to consider the influences under which the surfaces of planets are modelled and transformed.

Modern cosmogony is properly a department of physics and dynamics; but when states of matter irreproducible in the laboratory, and the mechanics of systems too complex for rigorous mathematical treatment, are dealt with, moderation in the general reasoning employed has not always been duly observed. No one can doubt that speculation is of the highest scientific importance, but it is also equally certain that in work of this kind a descending scale may be formed, beginning with speculations founded on rigorous mechanical principles and ending with wild and lunatic fancies. Every writer on such topics must, I suppose, sometimes question himself with misgiving as to where in such a list his name would stand. Mr. Winchell appears to treat all speculations with judgment, although one is sometimes tempted to think the exposition over-elaborate and the consideration too patient.

The first part or book is entitled "World-Stuff," and begins with a good account of meteors and meteoric dust. The author thinks that, according to Mr. Aitken's theory of the formation of fog, the highest clouds in our atmosphere reveal the presence there of a very fine dust, probably of cosmic origin. The sunset-glows of last winter appeared

to illuminate clouds at an unusual altitude: may not these clouds have owed their existence to the very dust which caused the glow?

The zodiacal light is then described, and is attributed to swarms of meteorites circulating round the sun, and the visibility of the light on both horizons simultaneously is taken as showing that the orbits of some of them are greater than that of the earth. The author also suggests the probability that swarms of meteorites circulate about the planets as satellites.

Comets, whose association with meteorites is now generally accepted, are described. Later (p. 77) the author writes:—

> "The phenomena of the tail, especially in the vicinity of aphelion, are such as would result if we could conceive the nucleus of the comet surrounded by an aura extending on all sides as far as the remotest limits of the tail, and could recognise the tail as merely a *luminous shadow* cast by the nucleus in intercepting certain radiant energy proceeding from the sun. . . . The tail would be, therefore, not a material form moving with the comet, but something perpetually renewed, while the older and more distant emanations disappear from visibility."

That theory which divides the tails of comets into three classes, according to the gas of which they are formed, is not given.[1]

The nebulæ are then passed in review, and are well illustrated by drawings. They are classified as amorphous, spiral, spiro-annular, annular, and planetary, and the class is taken as giving an indication of the stage of evolution.

In the case of a spiral nebula, such as that in Canes Venatici (Fig. 8, *op. cit.*), it seems difficult to believe that we view the whole. And we suggest that the great mass of the gas is non-luminous, the luminosity being an evidence of condensation along lines of low velocity, according to a well-known hydrodynamical law. From this point of view the visible nebula may be regarded as a luminous diagram of its own stream-lines.

In the second chapter the author enters on the generation of heat in nebular masses. The discussion appears unsatisfactory, and as it is a matter of primary importance, I propose to make some criticisms thereon. The usage of mechanical and thermic terms is loose, so that it is somewhat difficult to determine the author's meaning.

The question is concerning the generation of heat in a contracting nebular mass, and on p. 86, § 9, he concludes:—

> "It is true, then, that contraction develops heat, and that its development delays final refrigeration; that is, the progress toward final refrigeration is not as rapid as the amount of radiated heat implies. But it is not true that contraction (from cooling) can have developed the whole amount of heat at any time existing in the mass, or can even maintain a body at a constant temperature."

From this conclusion I venture to dissent, and in order to show my grounds I will give a paraphrase of the author's argument, as far as I am able to grasp it.

Let there be two similar planetary spheres with layers of equal density similarly arranged, and let the linear dimensions of the smaller (or say configuration β) be 1-nth of those of the larger (or say configuration a); or,

[1] This was sketched by Prof. Ball in his late lecture at Montreal, but I have unfortunately forgotten the originator's name

in other words, let a and a/n be any corresponding radii of α and β.

Let the mass, however, contained within radius a of α be equal to that within radius a/n of β; so that β might be formed from α by simple contraction; and suppose both systems to be in hydrostatic equilibrium. Then it is easy to show that if ρ be the density at any point of α, the corresponding density of β is $n^3\rho$; and if p be the pressure at the same point of α, the corresponding pressure of β is n^4p; and lastly, the modulus of elasticity being $\rho dp/d\rho$ at any point of α, the corresponding elasticity of β is $n^4\rho dp/d\rho$.[1]

Now if we suppose the mass to have contracted from a state of infinite dispersion to the configurations α or β, there must in each case be a certain exhaustion of potential energy of mutual attraction of matter, developing heat in the mass. Then it may be shown that if h is the exhaustion of energy of the matter within a radius a in passing from infinite dispersion to configuration α, the exhaustion of energy of the matter within a radius a/n in passing from infinite dispersion to configuration β is nh.[2] The same is also true of any stratum in course of its contraction. If we take a succession of configurations with radii infinity, 1, $\frac{1}{2}$, $\frac{1}{3}$, &c., in harmonic progression, a constant amount of heat will be generated in passing from any one configuration to the next.

Now let us suppose that in course of contraction neither convection, conduction, nor radiation takes place; then if the temperature in the condition of infinite dispersion be zero, and if the specific heat be constant, the temperature of any stratum a of α being θ, that of stratum a/n of β will be $n\theta$. In this case $\rho\theta$, being density multiplied by absolute temperature, becomes, in passing from α to β, $n^4\rho\theta$. If, therefore, the modulus of elasticity varies as density multiplied by temperature, we have the elasticity in β n^4 times that of α. But we have already seen that $\rho dp/d\rho$ is augmented in passage from α to β by the factor n^4. Hence the hypotheses as to arrangement of strata, specific heat, and law of elasticity are such as to insure equilibrium in every configuration, if it holds in any. This law of elasticity is that of the *isothermal* contraction of a so-called perfect gas.

Now Mr. Winchell's argument appears to me to be that, when there is loss of heat by radiation, there is necessarily deficiency of temperature to make up the elasticity, and thus equilibrium is impossible unless we look for heat from other causes. He does not seem to notice, however, that it will be far nearer the truth (if any such physical hypotheses can be said to be near thereto) to take the elasticity from the adiabatic contraction of the perfect gas, which we know to vary as $\rho^\gamma\theta$, where $\gamma = 1{\cdot}408$. With this law the argument breaks down. In any case the constancy of specific heat, the similarity of successive configurations, and the law of elasticity of "perfect" gases are untenable. In order, however, to do justice to the author I must point out that he attributes later the supply of heat to "conglomeration," which differs I presume from "contraction" in the supposed absence of hydrostatic equilibrium in successive stages, and in the irregularity of the masses concerned.

The paragraph in this chapter on nebular rotation appears to clothe the matter in an unnecessary mystery. Surely we may admit that the existence of a nebular mass with an absolute zero of resultant moment of momentum is highly improbable; and if the expanded nebula has finite resultant moment of momentum, then *must* the agglomerated nebula rotate. Even with zero momentum the nebula might perhaps divide into two portions with equal and opposite momenta.

We next come to paragraphs on nebular annulation and the "spheration" of rings. The intractability of these problems to mathematical treatment renders the discussion highly speculative, but the author seems to treat his subject with discretion.

The second main division of the work bears the title of "Planetology." An elaborate survey of the solar system is given, with a consideration of the arguments for and against the nebular hypothesis. The fact that the inner satellite of Mars revolves in a period shorter than that of the rotation of its planet is regarded as a great difficulty in the acceptance of Laplace's theory. Our author, whilst suggesting as an explanation a diminution of the primitive period through the influence of a resisting medium, refers favourably to the theory that solar tidal friction has retarded the planet's rotation whilst leaving the period of the satellite unaltered. I have myself regarded the fact of which we speak as a very striking confirmation of the importance of tidal friction in planetary evolution.

Faye's modification of the nebular hypothesis, in which the planetary annuli are supposed to arise in the interior of the nebula, is criticised by Mr. Winchell with some success. An account is also given of Spiller's theory. That author rejects the annuli entirely, and supposes the planets to arise by a combination of tidal action with centrifugal force. The formation of the planet is supposed to take place after the central mass has reached the condition of igneous fluidity.

"It is manifest that a separated planetary mass must produce a tidal swell of some magnitude upon the fluid central mass. . . . At some perihelion of the planet therefore—concurring perhaps with a conjunction of planets—the centrifugal tendency of the equatorial portion of the central fluid mass would exceed gravitation, and the tidal swell would be lifted bodily from connection with the central mass. . . ."[1]

Neptune generated Uranus, Uranus Saturn, and so on.

Now I venture to say that Spiller could not have made any numerical estimate of the efficiency of a planet's tidal action on the sun, or he could not have proposed this fantastic theory.[2] It would therefore hardly have seemed to me worth while to have referred to this passage had not Mr. Winchell stated that this theory might be regarded as a prototype of one of my own.

I had suggested that when the earth, then without a satellite, was rotating in four or five hours, the free period of oscillation of the fluid planet would be almost the same

[1] The reader acquainted with Laplace's theory of the earth's figure will have no difficulty in proving this, or even a simple acquaintance with hydrostatic principles will suffice.

[2] The exhaustion of a homogeneous sphere of mass M and radius a is $\frac{3}{5}\mu M^2/a$, where μ is the attractional constant. Hence for a heterogeneous sphere we have $\frac{16}{3}\pi^2\mu\int_0^a \rho^2 a^4 da$. If ρ becomes $n^3\rho$ and a becomes a/n, obviously the exhaustion becomes n times as great as before.

[1] P. 213, *op. cit.*

[2] For such an estimate see a paper "On the Tidal Friction of a Planet attended by several Satellites, &c." (*Phil. Trans.* Part 2, 1881). On p. 515 it is shown that, supposing the coefficient of viscosity in the sun to be the same as that in the earth, then the increase of earth's orbital moment of momentum due to earth's tides in the sun is 1/113000th part of that due to sun's tides on the earth. See also Table III. p. 526.

as the period of the solar semi-diurnal tide, and that the solar tide might undergo such kinetic augmentation as to rupture the planet. A piece torn off might form the moon. The suggestion was only thrown out tentatively, and it might perhaps have been better had it been suppressed. The whole essence of the suggestion lies, however, in the approximate identity of the free and forced periods of oscillation, and this reasoning has no place in Spiller's theory.

In considering the history of a cooling planet, the author is opposed to Sir William Thomson, and concludes that the surface would harden into a crust. It seems to me that the time is hardly ripe for a very confident opinion on the point.

A large place is given in this book to the influence of tides in the evolution of a planet. A description is given of the tidal retardation of planetary rotation and the recession of the satellite; and the chapter is in fact principally a *résumé* of my own papers. The author is at one with me in rejecting Prof. Ball's view, that an enormous exaggeration of marine tides can have taken place within geological history. He is inclined to adopt the view that the trends have been imparted to our great continents by means of the wrinkling consequent on tidal friction in a primitively viscous mass; but he hardly notes, as I pointed out, that if this be so we have to accept a continuous adjustment of the general ellipticity of the earth to a figure of equilibrium, without obliteration of the wrinkles. The suggestion is thus perhaps placed in almost too favourable a light.

On p. 282 Mr. Winchell speaks as though solar tidal friction is adequate to cause a sensible lengthening of the year, so that in earlier ages it was sensibly shorter. It is impossible to admit the correctness of this view, as I have elsewhere shown.[1]

In a section on orogenic forces we have, amongst much other interesting matter, an account of M. Favre's experiment, in which a layer of clay is placed on a tense elastic membrane, which is then allowed to contract: an illustration of many of the facts of mountain geology is thus furnished.

In the following chapter the author follows the various lines of argument by which limits are placed on the age of a planet, and by a subsequent geological discussion endeavours to derive a time scale; but I feel incompetent to judge of the worth of the conclusion. We may regret to find the revival in this place of Prof. Haughton's argument, viz. that the absence of a measurable nutation of 306 days proves the enormous antiquity of the elevation of Europe and Asia. The argument is, I think, worthless, as I believe that Prof. Haughton now admits.[2]

The principal topics dealt with in the rest of the book are the geology of the moon, the physical condition and habitability of other planets, and the final effects of tidal friction.

The fourth main division of the book is historical, and contains a review of the evolution of cosmogonic theories, with an exposition of the speculations of Kepler, Descartes, Leibnitz, Swedenborg, Kant, Lambert, William Herschel, and Laplace.

From the account which has now been given of this work it must be evident that Mr. Winchell set before himself a task of portentous magnitude, and that he has performed it conscientiously. The criticisms which have been made should not impair the conviction that the student of this group of subjects will find his work of great value. G. H. Darwin

[1] *Phil. Trans.* Part 2, 1881, p. 524: "From this it follows that, if the whole of the momentum of Jupiter and his satellites were destroyed by solar tidal friction, the mean distance of Jupiter from the sun would only be increased by 1 25000th (*misprinted* 1 2500th) part. The effect of the destruction of the internal momentum of any other system would be very much less."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Pentacrinoid Stage of Antedon rosaceus

In compliance with Prof. Herdman's request, I have to state that my experience—acquired during seven years of consecutive dredging in Lamlash Bay (1855-61)—is in entire accordance with his own. Although the most active period of reproduction in *Antedon rosaceus* is undoubtedly (as stated by Sir Wyville Thomson) the *early* part of the summer, so that the Pentacrinoids which spring from the ova then matured and fertilised are ready to drop off their stems in the succeeding autumn, yet I never failed to obtain *Pentacrinoids* in all stages, as well as *Antedons* still "in fruit," throughout the months of August and September. In fact, the whole of my study of this type—which, as regards the skeleton, is fully recorded in my memoir in the *Philosophical Transactions* for 1865, and of which, as regards the soft parts, a general account is given in the *Proceedings* of the Royal Society for 1876, was carried out during those months; my official duties keeping me in London until after the first week in August.

I may take this opportunity of directing the attention of those interested in Crinoidal structure (1) to a communication I have recently made to the Royal Society (*Proceedings*, May 29) on the Nervous System of the Crinoids; (2) to a paper by Prof. A. Milnes Marshall in the *Quarterly Journal of Microscopical Science* for July last; and (3) to a paper by Dr. Carl Jickeli of Jena, in the *Zool Anzeiger*, 7 Jahrgang, No. 170.—The doctrine I propounded on this subject nearly twenty years ago (that the quinquelocular organ contained in the centro-dorsal basin of *Antedon* is a *nerve-centre*, and that the radial cords issuing from it, which traverse the calcareous segments of the arms and pinnules, and give off branches to the successive pairs of muscles, are *nerve-trunks*), though supported by the experimental evidence which I published in 1876, and by the careful microscopic investigations of my son, Dr. P. Herbert Carpenter, has not been accepted by Zoologists generally; being for the most part either ignored altogether, or pooh-poohed as "evidently" fallacious, because inconsistent with homological theory. When I made my recent communication (1) to the Royal Society, summing up the very remarkable confirmatory evidence afforded by my son's inquiries, and referring (as Prof. Marshall had kindly enabled me to do) to the then unpublished results of his experiments (2), which entirely tallied with my own, Prof. Huxley, while admitting the strength of my case, remarked that the position I assign to the nervous system of the *Crinoidea* is as anomalous (in relation to that of Echinoderms generally) as it would be for a Vertebrate animal to have its spinal cord lying along its ventral surface. In reply, I asked, "What more proof *can* you ask for, of the nervous function of the quinquelocular organ and radial cords?" The only additional evidence that Prof. Huxley could suggest, was the result of electric stimulation. Before my paper was published in the *Proceedings*, I learnt (3) that this experiment had been actually tried four years ago by Dr. Jickeli, whose results entirely confirmed my doctrine.

It is to be hoped, therefore, that those who have so confidently and persistently clung to a homology, which is in direct contradiction to the most complete and conclusive proof that experiment can afford—supported as this is by the large body o

anatomical and histological evidence summarised in my recent paper—will now see that unless they can disprove the statements of Prof. Marshall, Dr. Jickeli, Dr. P. Herbert Carpenter, and myself, they are bound to admit my doctrine, and to show how their theoretical homology is to be reconciled with it.

WILLIAM B. CARPENTER

56, Regent's Park Road, London, N.W., November 3

Natural Science for Schools

THE thoughtful and suggestive paper of Prof. Armstrong in the last number of NATURE (p. 19) is to be commended to the attention both of science teachers and of the head masters of our schools. It is undoubtedly true that, with few exceptions, science is still either completely neglected by our schools or handled in a way which does not at all tend to advance its interests. When it is made a "refuge for the destitute," or considered only fit for those intellectually unequal to the study of classics and mathematics, no wonder that observant head masters conclude that little good is to be got from it.

As a science master of many years' experience (having been in fact responsible for the introduction of science into *two* of the schools named by Prof. Armstrong as exceptions to the universal indifference), you will perhaps allow me to call attention to the importance of Prof. Armstrong's paper, and to give the conclusions to which my own experience has led me.

The importance of clearly understanding the purpose with which science is to be studied, and the distinction to be borne in mind between the best curriculum for those who are to be professed chemists and those who will not carry the study of chemistry beyond their school-days is obvious; but I wish to point out how entirely science masters are at the mercy of examiners, both of University examiners, periodically examining a school, and of examiners for open scholarships. My own experience is to the point. Fully persuaded of the uselessness of attempting to make an analytical machine out of the ordinary school-boy giving two or three hours a week to chemistry for two or three years, and of the very small amount of education to be obtained from such a course, I endeavoured to model my instruction in practical chemistry much upon the lines adopted by Prof. Armstrong, and exemplified in the appendix to his paper. When the examinations came, it was duly explained to the examiner that the course of instruction adopted had been unusual, but, all the same, the papers set were of the usual kind:—"Analyse the mixture A," "Determine the metals and acids present in the solution B," &c. On such a paper, of course, the boys failed, and a depreciatory report was sent up by the examiners, with the result that the governors of the school thought it their duty to interfere, and request that "more attention should be given to practical chemistry." Consequently my attempt had to be abandoned, and we returned to our "test-tubing."

Scholarship examinations, being presumably of those who will carry the study much further, may more reasonably demand a knowledge of the ordinary methods of analysis, but I am glad to see that a considerable change has taken place in the papers set, and that now the questions proposed are often such as to place the mechanical analyst at a disadvantage, and to encourage the intelligent observation and interpretation of phenomena.

Prof. Armstrong of course writes as a chemist. But there can be no doubt that certain portions of physics are educationally more useful, and it seems to be only the difficulty of arranging practical work in physics which has led to the present state of things, where practical science work in schools means nearly always practical chemistry. But Prof. Armstrong's protest against allowing this to degenerate into "test-tubing" should not be disregarded. There seems also no reason why *elementary* instruction in science—whether chemistry, or botany, or physiography—should not deal *first* with the familiar things of every-day life. I think much more training is to be got by determining, as Prof. Armstrong suggests, the composition of air, the relative combining weights of silver and lead, &c., than by seeing made any number of oxides of nitrogen, and listening to a description of their properties. There is, however, considerable difficulty in arranging easy methods of determining chemical equivalents which, in inexperienced hands, shall give results not *too wide* of the mark.

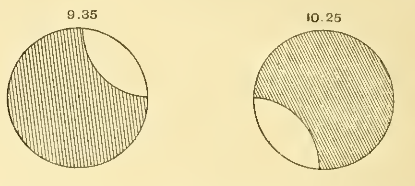
If a boy gets out the atomic weight of oxygen as 9 when the book says it is 16, or finds the latent heat of steam to be 300 and something when it ought to be 536, he begins to disbelieve in the precision of the statements made, and it is unfortunately impossible for a beginner to make *accurate* determinations of combining weights. Less erratic results can, in fact, be obtained in certain selected physical measurements.

The "bareness" of printed instructions is, as Prof. Armstrong remarks, a distinct advantage to the good student, by compelling him to think for himself, but it is fatal to the unintelligent student, to whom "thinking" is the very hardest work he is called upon to do.

SCIENCE MASTER

The Recent Lunar Eclipse

My object in writing is to confirm in some degree the peculiar appearance of the disk, noticed in your last number (vol. xxx. p. 632). The eclipse was seen here under the most favourable circumstances: the obscuration was so great that the disk could barely be discerned with the naked eye, and the copper colour usually seen was not noticed. Having watched the moon well into the umbra, my attention was diverted for a while, but, on looking again, at 9.35 G.M.T., I was surprised to see a portion of the north-east quadrant pretty strongly illuminated; my attention was again diverted, but on looking a second time at 10.35 G.M.T., I observed a portion of the south-east quadrant



illuminated in a somewhat similar manner. At both times the moon was well within the geometrical umbra. But the remarkable feature was that on both occasions the boundaries of the illuminated portions were, approximately, circular, and convex toward the axis of the umbra, indicating that the refracted solar rays producing these illuminations had crossed the axis of the shadow-cone previous to impinging on the lunar disk. The portions of the refracting annulus of the earth's atmosphere concerned in producing these effects were those superincumbent on the Southern Indian Ocean and the North Atlantic.

The Sky-Glows

IN using the word "corona" to designate the coloured glare which has accompanied the sun during the past year, I had no intention of employing it in its astronomical sense, but in its ordinary meteorological meaning—which "G. M. H." (NATURE, vol. xxx. p. 633) has overlooked—as referring to the coloured circles on cloud and haze frequently to be seen round the sun and moon, and classed by some observers with halos. By calling the circle now visible round the sun a "corona," I mean that in appearance and probable optical cause it is more like a meteorological corona than like a halo.

May I be allowed to point out a misprint in the first paragraph of my last letter (vol. xxx. p. 633), where it should read "unusual sky phenomena"—the world *universal* having been printed for *unusual*.

T. W. BACKHOUSE

Sunderland, November 8

AFTER sunset this evening there was a peculiar pink flush in the western sky here similar to that which attracted so much attention in England last year. Twenty-five minutes after the sun had gone down, the colour was so vivid as to be reflected from the snows of Mount Baker (10,700 feet), which is about seventy-five miles east of this place. Shortly afterwards it disappeared, but reappeared thirty-five minutes later, prolonging the twilight and making the stars look green, finally dying away very gradually. The weather for the past twelve days has been very wet, and to-night's is the first clear sunset in that time.

Fourteen days ago, when on the Fraser River, eighty miles from here, I saw after sunset a very brilliant aurora borealis. I write this thinking there may be a repetition of the phenomena in England, in which case this note may possess interest.

Peculiar Ice Forms

THE ice structures observed by Mr. Woodd Smith (November 6, p. 5) are evidently the same as were described in vol. xxi. p. 396. I have often seen such fibrous masses since, under circumstances which left no doubt of their being mainly due to prolonged condensation of aqueous vapour from the air; the fibres, white like asbestos, and covered only by a very thin layer of earthy particles, rising from a hard subsoil. The absorption of aqueous vapour by the soil, especially on mountains, seems not yet to be duly appreciated, although it is proved by the many springs issuing at short distances below the summits, and has been insisted upon already in Er. Darwin's "Botan. Garden" and "Phytonomia" (chap. xi. 2). "Rainfall being the source of all water-supply" (NATURE, vol. xxx. p. 375) is a statement hardly to be maintained.

Seismographs—An Apology

I AM just in receipt of the inclosed letter from Mr. Charles A. Stevenson, in which he claims the original idea of the actuating mechanism in the *horizontal component seismograph* I have lately described in these pages, and he includes a copy of his paper to justify his remarks. I therefore think it my duty to offer my apologies to him for not having given him full credit for his invention so far as it goes, although I have *unconsciously* done him wrong. Naples is unfortunately very badly off for modern scientific works and *Proceedings* of Societies, both as regards the National and the University libraries, and as far as I know no copy of Mr. Stevenson's paper exists in the town, except the one he has now sent me.

Perhaps I may be permitted to point out that Mr. Stevenson's seismograph, so far as it is described, would be almost useless for the following reasons:—

(1) The inertia of the upper glass plate would be insufficient not to be affected by the slight movement conducted through the ivory balls to it. This is the reason I use the very heavy lead disk.

(2) No earthquake shock is perfectly horizontal, so that Mr. Stevenson's instrument would only be fit to register the horizontal component of the earth-wave, and would fail to do this, since if the angle of emergence was appreciable it would be jerked up off its supports, and consequently would simply register a series of interrupted lines. This is why I introduced the upper balls and resistance plate.

(3) If the instrument was disturbed by an earth-wave of large amplitude, the registering arm would pass beyond the border of the smoked plate (unless the apparatus was of very great dimensions, so failing to fulfil the conditions of the British Association), where the needle would drop out, or fall so low as to prevent the return of the arm over the plate.

(4) If the earthquake was of some seconds' duration and composed of many varying movements, as is generally if not always the case, a network of irregular curves would remain on the glass that would be quite unintelligible.

If a thing is to be done, it is advisable to do it well, and it is less possible to have accurate registers of earthquake shocks than of the force and direction of the wind, barometric pressure, or any other meteorological phenomena. The requirements of the British Association with regard to expense, size, and portability of seismographs, will not permit anything like an accurate investigation of geodynamics.

In conclusion, should I have overlooked and appropriated the ideas of any other inventor, I shall be happy to fully acknowledge them if sufficient evidence is given (as in the above case) of priority of publication.

H. J. JOHNSTON-LAVIS

November 7

45, *Melville Street, Edinburgh, November* 3

I NOTICED recently in NATURE (vol. xxx. p. 608) an article by you in which you describe a seismograph for recording earthquake shocks, which would appear to be your own invention from reading the paper. No doubt the method of making the record, springs, and upper balls are your own invention, but the *principle* on which the seismograph there described acts is, as far as I know, mine or my father's. I inclose the paper in which it was first described, and I would be glad to learn from you if you forestalled me.

CHARLES A. STEVENSON

Dr. Johnston-Lavis, Naples

Fly-Maggots Feeding on Caterpillars

A FEW months ago I had a caterpillar of *Papilio erythronius*, which I found on a lemon-tree. I put it into a card-box, and fed it daily on lemon-leaves. The box was covered with cloth *tied tightly all round the opening*. After some days, the caterpillar fixed itself to the side of the box, and turned into a chrysalis in the usual way. One day on opening the box, instead of finding the chrysalis changing into its usual colours and markings, it was dark all over. A few days more, on re-opening the box, I found six fully-developed cream-coloured maggots at the bottom of the box. I was rather puzzled to conjecture how these maggots got into a box three inches high, with a bit of cloth tied all round the opening. I put the maggots into a little box with some earth under a tumbler. They immediately buried themselves in the earth. In a few days I found six chrysalides, and some days later there were six ordinary house-flies buzzing within the tumbler. I then examined the dark chrysalis of the *P. erythronius*, which was evidently dead, and found it only a *shell*. All its interior had been consumed by the six maggots. It is evident that these maggots in their infant stage had already been in the body of the caterpillar when I boxed it. The latter had gone through its transformation as if nothing was the matter with it, although, if one could have interrogated it, probably it would have complained of mysterious gnawings and creepings in its interior. A time, of course, came when, for want of nerve-centres and other organs, the chrysalis could not go on with its development into the perfect Papilio. The six maggots having had a full meal, found their way out of the Papilio's chrysalis in order to undergo *their* transformation.

I knew that the larvæ of the Ichneumonidæ fed on the live bodies of caterpillars, but I did not know that the larvæ of the house-fly did so also.

Etawah, India, October 18

THE CRYSTALLINE ROCKS OF THE SCOTTISH HIGHLANDS

EVER since the discovery of Silurian fossils in the rocks of North-West Sutherland, it has been recognised that in that region lies the key to the structure of the Scottish Highlands. Accordingly, when in the progress of the Geological Survey, the mapping of the Highlands had to be undertaken, I determined that a detailed survey of the Sutherland ground on the scale of six inches to a mile should be made as a basis for the work. In the summer of last year a surveying party under the charge of Mr. B. N. Peach was stationed there, with instructions to begin by mapping the Durness Basin. This duty was satisfactorily accomplished before the end of the season. The Silurian series of Durness was ascertained to be about 2000 feet thick, and to consist of numerous successive zones, which were traced on the six-inch maps and discriminated in such a way as to be recognisable should they be found to occur in the more complicated region to the east. With this necessary groundwork well established, the Eriboll tract was attacked this summer by Messrs. Peach and Horne. I had never myself had an opportunity of studying the Eriboll sections, which, from the days of Macculloch down to the present time, have been such a fruitful subject of discussion. It was a special injunction to the officers now intrusted with the detailed survey of the region to divest themselves of any prepossessions in favour of published views and to map the actual facts in entire disregard of theory. By the close of this last season the structure of the Eriboll area had likewise been traced upon the six-inch maps, and I then went north to inspect the work. From time

to time during the summer, reports had been made to me of the progress of the survey, but, though from the published descriptions of that tract, I was aware that its structure must be singularly complicated, and although apprised of the conclusions to which the surveyors, step by step and almost against their will, had been driven, I was hardly prepared for the extraordinary geological structure which the ground itself presented, or for the great change necessitated in the interpretation of the sections as given by Murchison.

No one cursorily visiting the ground could form any notion of its extraordinary complication, which could only be satisfactorily unravelled by patient detailed mapping such as had never yet been bestowed upon it. With every desire to follow the interpretation of my late chief, I criticised minutely each detail of the work upon the ground; but I found the evidence altogether overwhelming against the upward succession which Murchison believed to exist in Eriboll from the base of the Silurian strata into an upper conformable series of schists and gneisses. The nature of this evidence will be best understood from the subjoined report, which, at my request, Messrs. Peach and Horne have prepared. As the question of the succession of the rocks in the North-West Highlands is still under discussion, I think it right to take the earliest opportunity of making this public declaration. It would require more space than can be given in these pages to do justice to the views of those geologists, from Nicol downwards, by whom Murchison's sections have been criticised, and to show how far the conclusions to which the Geological Survey has been led, have been anticipated. When the official memoirs are published, full reference will be given to the work of previous observers, to which, therefore, no further allusion is made at present.

The most remarkable features in the Eriboll area are the prodigious terrestrial displacements, to which there is certainly no parallel in Britain. Beginning with gentle foldings of the rocks, we trace these becoming increasingly steeper on their western fronts, until they are disrupted and the eastern limb is pushed westwards. By a system of reversed faults, a group of strata is made to cover a great breadth of ground and actually to overlie higher members of the same series. The most extraordinary dislocations, however, are those to which for distinction we have given the name of Thrust-planes. They are strictly reversed faults, but with so low a hade that the rocks on their up-throw side have been, as it were, pushed horizontally forward. The distance to which this horizontal displacement has reached is almost incredible. In Durness, for example, the overlying schists have certainly been thrust westwards across all the other rocks for at least ten miles. In fact, these thrust-planes, but for the clear evidence of such sections as those of Loch Eriboll, could not be distinguished from ordinary stratification-planes, like which they have been plicated, faulted, and denuded. Here and there, as a result of denudation, a portion of one of them appears capping a hill-top. One almost refuses to believe that the little outlier on the summit does not lie normally on the rocks below it, but on a nearly horizontal fault by which it has been moved into its place. Masses of the Archæan gneiss have thus been thrust up through the younger rocks and pushed far over their edges. When a geologist finds vertical beds of gneiss overlying gently inclined sheets of fossiliferous quartzite, shale, and limestone, he may be excused if he begins to wonder whether he himself is not really standing on his head.

The general trend of all these foldings and ruptures is from north-north-east to south-south-west, and the steep westward fronts of the folds show that the terrestrial movement came from east-south-east. Corroborative evidence that this was the direction of the movement is furnished by a series of remarkable internal rearrangements that have been superinduced upon the rocks. Throughout the whole region, in almost every mass of rock, altogether irrespective of its lithological characters and its structure, striated planes may be noticed which are approximately parallel with the thrust-planes, and are covered with a fine parallel lineation, running in a west-north-west and east-south-east direction. These surfaces have evidently been produced by shearing. Again, many of the rocks near the thrust-planes, and for a long way above them, are marked by a peculiar streaked structure which reminds one of the fluxion-lines of an eruptive rock. The coarse pegmatites in the gneiss, for example, as they come within the influence of the shearing, have had their flesh-coloured feldspar and milky-quartz crushed and drawn out into fine parallel laminæ till they assume the aspect of a rhyolite in which fluxion-structure has been exceptionally well developed. The gneiss itself coming into the same powerful mill has acquired a new schistosity parallel with the shearing-planes. Hornblende-rock has been converted into hornblende-schist. Moreover, new minerals have likewise made their appearance along the new divisional planes, and in many cases their longer axes are ranged in the same dominant direction from east-south-east to west-north-west.

Murchison believed that the Silurian quartzites and limestones of Eriboll pass up under, and are conformably overlain by, his upper gneiss. It is quite true that they are so overlain; but the overlying rocks, instead of having been regularly deposited on them, have been pushed over them. What, then, are these overlying rocks? Though they have undergone such intense alteration during the process by which they were moved into their present position that their original characters have been in great measure effaced, lenticular bands occur in them which can certainly be recognised. Some of these bands are unquestionably parts of the Archæan gneiss; others are Silurian quartzite, and in one case we can detect a large mass of the Upper Durness limestone. Traced eastwards, however, the crystalline characters become more and more pronounced until we cannot tell, at least from examination in the field, what the rocks may originally have been. They are now fine flaggy micaceous gneisses and mica-schists, which certainly could not have been developed out of any such Archæan gneiss as is now visible to the west. Whether they consist in part of higher members of the Silurian series in a metamorphic condition remains to be seen. The occurrence of a band of crystalline limestone and calcareous schist, which has been traced for many miles above the great thrust-plane, certainly suggests that it represents the upper part of the calcareous Durness series attenuated and altered by the intense shearing which all the rocks have undergone. This much at least is certain, that the schistose series above the thrust-plane is partly made up of Silurian strata, and has received its present dip and foliation since Silurian time.

Having satisfied myself that Murchison's explanation of the order of sequence could not be established in Eriboll, I was desirous to see again, in the new light now obtained, some of the Ross-shire sections for the description of which I am responsible. Had these sections been planned for the purpose of deception they could not have been more skilfully devised. The parallelism of dip and strike between the Silurian strata and the overlying schists is so complete as to prove the most intimate relationship between them; and no one coming first to this ground would suspect that what appears to be a normal stratigraphical sequence is not really so. But the clear coast-sections of Eriboll, where every dislocation is laid bare, have now taught me that I have been mistaken, for the parallelism in question is not due to conformable deposition. The same kind of evidence of upthrust and metamorphism which these coast-sections reveal can be traced southwards for a distance of more

than ninety miles. The task of unravelling the geological structure of these southern regions will be much facilitated by the remarkable persistence of the Sutherland Silurian zones, some of which, with their characteristic features and fossils, are as well marked above Loch Carron as they are at Loch Eriboll.

In south-western Ross-shire the platform on which the Silurian rocks rest is a thick mass of Cambrian red sandstone. In the great upthrow, it is this sandstone platform which has there been pushed over the limestones and quartzites. On the west side of Loch Keeshorn, the red sandstones, in their normal unaltered form, rise up into the colossal pyramids of Applecross; but on the east side, where, at a distance of little more than a mile, they overlie the limestones, they bear so indurated an aspect that they have naturally been classed with the quartzose members of the Silurian series. Traced eastwards they present increasing evidence of intense shearing; fluxion-structure makes its appearance in them, with a development of mica along the divisional planes, until they pass into frilled micaceous schist, in which, however, the original clastic grains are still recognisable. They finally shade upwards into green schists and fine gneiss which merge into coarse gneiss with pegmatite. The short space within which ordinary red feldspathic sandstone and arkose acquire the characters of true schists is a point of some importance in regard to the change from the unaltered Silurian strata of the Southern Uplands into the metamorphic condition of the Highland phyllites, grits, &c.

Obviously the question of chief importance in connection with the structure now ascertained to characterise the North-West Highlands relates to metamorphism. That there is no longer any evidence of a regular conformable passage from fossiliferous Silurian quartzites, shales, and limestones upwards into crystalline schists, which were supposed to be metamorphosed Silurian sediments, must be frankly admitted. But in exchange for this abandoned belief, we are presented with startling new evidence of regional metamorphism on a colossal scale, and are admitted some way into the secret of the processes whereby it has been produced.

From the remarkably constant relation between the dip of the Silurian strata and the inclination of their reversed faults, no matter into what various positions the two structures may have been thrown, it is tolerably clear that these dislocations took place before the strata had been seriously disturbed. The persistent parallelism of the faults and of the prevailing north-easterly strike of the rocks indicates that the faulting and tilting were parts of one continuous process. The same dominant north-easterly strike extends across the whole Highlands, and also over the Silurian tracts of Southern Scotland and the North of England. There is reason to regard it in all these regions as probably due to one great series of terrestrial movements. These must have occurred some time between an early part of the Silurian period and that portion of the Old Red Sandstone period represented by the breccias and conglomerates of the Highlands. In the Central and Eastern Highlands the slates, phyllites, grits, quartzites, and limestones which, along the southern border, are scarcely more altered than their probable equivalents among the Silurian rocks of the Southern Uplands, have been greatly plicated, and have assumed a more or less crystalline structure. But when these changes were brought about, there lay to the north-west a solid ridge of Archæan gneiss and Cambrian sandstone which offered strong resistance to the plication. The thrust from the eastward against this ridge must have been of the most gigantic kind, for huge slices, hundreds of feet in thickness, were shorn off from the quartzites, limestones, red sandstones, and gneiss, and were pushed for miles to the westward. During this process, all the rocks driven forward by it had their original structure more or less completely effaced. New planes, generally parallel with the surfaces of movement, were developed in them, and along these new planes a rearrangement and recrystallisation of mineral constituents took place, resulting in the production of crystalline schists. This metamorphism certainly occurred after early Silurian times, for Cambrian and Lower Silurian strata, as well as Archæan rocks, have been involved in it.

It is obvious that into the problems of Highland geology, always admittedly obscure, a fresh element of difficulty is introduced. At the same time the aid furnished by a minute study of the Sutherland sections is so great that we may hope to attack these problems with more success than has hitherto seemed probable. The work, too, is not of a kind to be attempted in a few hasty scampers over the ground. It will require patient detailed mapping. But when the great base-lines have once been accurately traced, the difficulties will doubtless begin to diminish, and, like the pieces of a puzzle, the various segments of the Highlands will then be found to range themselves in their proper places. ARCH. GEIKIE

Report on the Geology of the North-West of Sutherland

In the north-west of Sutherland the most ancient rocks belong to the Archæan series, and present a great uniformity in lithological characters. They consist mainly of coarse hornblendic gneiss, with distinct zones of gray and pink granitoid gneiss, in which the mica is more abundant than the hornblende. Lenticular veins and bosses of hornblende-rock and hornblende-schist, some at least of which are evidently intrusive, occur in the gneiss, while the presence of small kernels of cleavable hornblende and actinolite forms another characteristic feature of the series. Veins of pink or white pegmatite abound, sometimes parallel with the foliation of the gneiss and sometimes traversing it in all directions. These, however, are distinct from dykes of pink granite, which also intersect the gneiss and coarse pegmatites, and are themselves crossed by later pegmatite-veins. Here and there, indeed, the branches of a pegmatite-vein can be seen to return upon themselves and traverse the main trunk from which they start. Where the Archæan rocks have been recently stripped of their former cover of Silurian quartzite, bands of green epidotic gneiss appear among them, and a soft green mineral with a greasy lustre (agalmatolite ?) is there characteristic of the superficial parts of the pegmatite-veins.

The highly crystalline Archæan rocks are overlain unconformably by a succession of conglomerates, grits, and sandstones, regarded by Murchison as the equivalents of the Cambrian system of Wales. In the course of the work of the Geological Survey in the present region they have been divided into certain zones, which, though they need not be stated here, as they have no bearing on the main question to which this paper is devoted, may prove to be of considerable importance in unravelling the geological structure of the districts further south.

Between the Cambrian sandstones and the overlying quartzites at the base of the Silurian series there is a complete discordance. To the west of the Kyle of Durness, for example, the Cambrian sandstones dip to the north-west, while the overlying quartzites dip to the south of east. Moreover, as the observer passes eastwards to the shores of the Kylê, the Cambrian sandstones are bed after bed transgressed by the quartzites, which eventually rest directly on the Archæan gneiss. The Silurian strata in the Durness area (A in Section) consist of a calcareous series at the top; a middle series, composed partly of calcareous and partly of arenaceous strata; and an arenaceous series at the base. The various sub divisions of the strata are given in descending order in the subjoined tabular statement.

C. Calcareous Series ...	VII. Durine Group ...	Fine-grained, light gray limestones, with an occasional dark fossiliferous band.
	VI. Croisaphuill Group	*c.* Fine-grained, cleaved, lilac-coloured limestones, full of flattened worm-casts; fossils distorted by cleavage. *b.* Alternations of black, dark gray, and white limestone, with an occasional fossiliferous band, like zone (*a*) of this group. *a.* Massive, dark gray limestone, chiefly composed of worm-casts which project above the matrix on weathered surfaces. Near the base are several lines of small chert nodules. This is one of the most highly fossiliferous zones in the Durness Basin.
	V. Balnakeil Group ...	Alternations of dark and light gray limestone, highly fossiliferous, with occasional impure, argillaceous, unfossiliferous bands. Most of the beds are distinctly cleaved, and contain few worm-casts.
	IV. Sangomore Group...	Fine granular dolomites, alternating near the top with cream-coloured or pink limestone. Near the base are two or more bands of white chert, one of which is about 5 feet thick.
	III. Sailmhor Group ...	Massive, crystalline-granular, dolomitic limestones, occasionally fossiliferous, charged with dark worm-castings set in a gray matrix; large spheroidal masses of chert near the base. This limestone is locally known as "the Leopard Stone."
	II. Eilean Dubh Group	Fine-grained, white, flaggy, argillaceous limestones and calcareous shales. As yet no fossils have been found in this division.
	I. Ghrudaidh Group ...	Dark leaden-coloured limestones, occasionally mottled, alternating near the top with white limestone. About 30 feet from the base there is a thin band of limestone charged with *Serpulites Maccullochii*, and a similar band occurs at the base.
B. Middle Series (partly calcareous and partly arenaceous)...	Upper Zone	At the base lies a massive band of quartzite and grit, passing upwards into carious dolomitic grit, crowded in patches with *Serpulites Maccullochii*, more especially in the decomposed portions (Serpulite-Grit).
	Middle Zone	Alternations of brown, flaggy, calcareous, false-bedded grits and quartzites with cleaved shales.
	Lower Zone	Calcareous mudstones and dolomitic bands, weathering with a rusty brown colour, traversed by numerous worm-casts, usually flattened, and resembling fucoidal impressions. These beds are often highly cleaved. This and the overlying zone form the "Fucoid-beds" of previous authors.
A. Arenaceous Series...	Upper Zone	Fine-grained quartzites, perforated by vertical worm-casts and burrows becoming more numerous towards the top of the zone ("pipe-rock" of previous authors). These beds pass downwards into massive white quartzites.
	Lower Zone	False-bedded flaggy grits and quartzites, composed of grains of quartz and feldspar. At the base there is a thin brecciated conglomerate, varying from a few inches to a few feet in thickness, containing pebbles of the underlying rocks, chiefly of quartz and orthoclase, the largest measuring about 1 inch across.

The Silurian strata in the Durness area are arranged in the form of a basin, truncated on the east side by a fault that brings them against the Archæan gneiss, and thus disconnects them from the Eriboll area, with which they were certainly at one time united. Of the identity of these strata in the two areas there cannot be the smallest doubt. We have recognised them zone by zone, completing the proofs of this identity by detecting in the south and central parts of the Durness Basin the representatives of the middle series, viz. the "Fucoid-beds" and "Serpulite-grit," which had not previously been noted in that area. Though subject to local variations in thickness, these zones are singularly persistent, and, from their marked lithological characters and fossil contents, constitute admirable horizons in unravelling the complicated geological structure of the region. A rich assemblage of fossils has been obtained by the Survey from the various fossiliferous bands indicated in the foregoing table, comprising Trilobites, Annelids, Cephalopods (*Nautilus*, *Lituites*, *Orthoceras*, *Piloceras*, &c.), Heteropods, Gasteropods, Lamellibranchs, Brachiopods, Corals, Sponges, and Foraminifera. As yet this collection has not been examined in detail, but from observations in the field it is probable that some of the limestone zones will be found to be characterised by particular fossils.

A striking feature of the Durness Basin is the amount of displacement of the strata by faults; indeed, this feature is so characteristic of the highest limestone zones that it is difficult satisfactorily to compute their thickness. But from the base of the quartzite to the top of the calcareous series the total thickness of Silurian strata cannot be less than 2000 feet. In Sangomore Bay, near the village of Durine, the highest limestone zone is overlain by shattery quartzite, striped fissile schist, frilled schists, and gneiss. Though unquestionably resting upon the limestone and sharing in the normal faulting of the district, these crystalline strata do not prove a conformable upward succession, as has been naturally enough supposed. The key to the reading of this and of the corresponding section at Farrid Head is to be sought in the Eriboll tract.

The Silurian rocks of the Durness Basin are separated from those of Loch Eriboll (B in the Section) by a prominent ridge of Archæan gneiss, the eastern slope of which is covered by a cake of quartzite. Along the crest of the chain the basal breccia is exposed, overlain by the lower zone of false-bedded grits (No. 3) and the upper zone of "pipe-rock" (No. 4 in Section). As the eastern declivity of the ridge is greater than the dip of the quartzites, the observer, on descending the slope, crosses the basset edges and dip-slopes of the latter strata, and eventu-

ally finds himself again on the old platform of Archæan gneiss exposed by denudation (see Section). Both the zones of quartzite are then once more met with in their normal order, the highest beds exposed on the western shore of Loch Eriboll belonging to the horizon of the "pipe-rock." On the eastern shore, at Ant Sron, on the crest of a low anticlinal arch of the "pipe-rock," there is an excellent section of the middle series between the quartzites and the limestones. The two subdivisions of the "Fucoid-beds" (No. 5) and the "Serpulite-grit" (No. 6 in Section), which are typically developed at that locality, pass underneath the Serpulite-limestone at the base of Group I., exactly as they do at Durness. The dark leaden-gray limestones of the lowest group (I.) are then rapidly succeeded by flaggy limestones (Ant Sron, Chorrie Island, Heilim) and dolomitic limestones which, probably the equivalents of the Eilean Dubh Group in Durness, are the highest members of the series here represented (No. 7 in Section). A careful search among the Eriboll limestones has failed to bring to light any organic remains save *Serpulites* and certain minute spherical bodies which may prove to be Foraminifera. A similar dearth of fossils characterises the two lowest zones in Durness, so that this feature is common to both areas. The non-occurrence of the higher fossiliferous limestones in Eriboll may be accounted for by the remarkable geological structure of that region which is now to be described.

As the observer passes eastwards along the magnificent quartzite sections on Crag Dionard and Conamheall, south of Loch Eriboll, he cannot fail to note the numerous flexures of the strata, and especially the peculiar type of their sharp anticlinal folds. As a rule, the eastern limb of each of these folds dips at a gentle angle to the south-east, while the west limb is highly inclined, vertical, even inverted, or sometimes broken by a reversed fault the effect of which is to bring lower over higher beds. These reversed faults (*t t t* in Section) become more numerous eastwards. They are admirably displayed both in ground-plan and dip-section on the shore north of Heilim, where they repeat the various zones ranging from the "pipe-rock" to the Eilan Dubh limestone (Group II.). The strike of the reversed faults ranges on the whole with that of the strata traversed, and their hade is inclined at a higher angle than the dip of the latter, the difference generally amounting to about 10°. Inland from the coast-section, north of Heilim, to the base of Ben Arnaboll, the zones just mentioned are constantly repeated by a complicated system of reversed faults and folds, the general inclination of the strata being towards the south-east. As that hill is approached, the displacement produced by these faults increases in amount; hence the observer meets with beds occupying a lower geological horizon the further east he travels. At length this intricate system of faults and folds culminates in a great dislocation which, for convenience

of description, and to distinguish it from the ordinary reversed faults, may be termed a *Thrust-plane*. By means of it a great mass of coarsely crystalline gneiss with pegmatite-veins, in places upwards of 400 feet thick, is placed above the Silurian rocks (see Section). A careful examination of the mass which caps Ben Arnaboll clearly proves that *it rests transgressively on all the zones of the Silurian rocks, from the lower zone of the quartzites (false-bedded grits) up to the limestone which overlies the Serpulite-grit.* Owing partly to its low hade and partly to subsequent folding, the outcrop of this thrust-plane resembles that of an ordinary overlying formation cut into a sinuous line by denudation. It is admirably seen in dip-section on the east and north slopes of Ben Arnaboll, whence it can be followed round the west face of the hill, descending into the valley on the west, then bending back on itself, winding round the north slope of Druim Tungi, and entering Loch Eriboll in Heilim Bay. It reappears at the base of Crag-na-Faolinn, and has been traced still farther to the south, while northwards it can be followed to the Whitten Head, at the mouth of Loch Eriboll.

That the gneiss thus brought up on Ben Arnaboll and elsewhere is in reality the Archæan gneiss is evident, for two reasons. First, its lithological characters agree with those of the typical Archæan area to the west, save in certain cases where the original features have been effaced by the crushing to be afterwards described. Near the thrust-plane, this effacement is complete, but in the heart of the mass the normal characters of the Archæan rocks, including in some instances their characteristic north-west strike, are retained. The rocks consist of coarsely crystalline hornblendic gneiss and pink granitoid gneiss, with lenticular veins of hornblende-rock and kernels of cleavable hornblende, while massive veins of pink pegmatite are well developed. The soft greenish mineral (agalmatolite?) already mentioned as characteristic of the gneiss, where now or lately covered with quartzite, occurs here in the pegmatites, and veins of epidosite are abundant. Second, at various localities the brecciated conglomerate and false-bedded quartzite at the base of the Silurian strata are found resting on these crystalline rocks. Further, the unconformable junction can on one line be traced continuously for more than a mile. There can be no doubt, therefore, that this mass is really a fragment of the old platform of Archæan rocks on which the Silurian strata were deposited.

The occurrence of this Archæan gneiss in its present position above much younger rocks is doubtless to be ascribed to the same cause which elsewhere has resulted in foldings of the strata. In the present instance we see an attempt, as it were, to establish an anticlinal fold of the type already described as occurring to the west, with a steep westward and gentle eastward slope. The west limb however has here given way along a great dislocation or reversed fault, while the eastern limb has been driven forwards until the Archæan rocks have been carried over the truncated edges of the Silurian strata. The vertical beds of the basal quartzites are still

to be seen on the west limb of the anticline on Ben Arnaboll, Crag-na-Faolinn, and on Whitten Head (see Section). The quartzites on Druim Tungi, and indeed all the Silurian strata on the east side of Loch Eriboll, between Heilim and Crag-na-Faolinn, form part of a syncline which has been pushed westwards in front of the anticline along this thrust-plane. This structure explains the origin of the inversion of the Silurian rocks along the junction line east of Camas-an-Duin, and the occurrence of the lower limestone groups in a shallow trough at Eriboll. Of special interest is the occurrence of a small outlier of Archæan gneiss on the crest of a hill (Sitheanna-Cuag) north-west of Ben Arnaboll. This mass rests on the Fucoid-shales, Serpulite-grit, and limestone. Though now isolated by denudation, it was obviously originally continuous with the mass on Ben Arnaboll, and it thus furnishes striking proof of the westward extension of displaced gneiss, and of the thrust-plane on which it travelled.

The effects of this great movement on the Silurian strata which have been over-ridden by the gneiss are somewhat remarkable. The pipes or vertical worm-tubes in the quartzites have been flattened, drawn out, and bent over in a direction perpendicular to the strike of the thrust-plane. The false-bedded grits and quartzites present a streaky appearance resembling fluxion-structure, due to the elongation of the fragments of orthoclase-feldspar and the quartz grains. The fine-grained rocks, especially the compact quartzites and the Fucoid-beds, are highly cleaved, the strike of the cleavage-planes being parallel with that of the thrust-plane, and this parallelism being maintained quite irrespective of any variation in the direction of dip of the strata next the gneiss. On the surface of the cleavage-planes also there is a series of parallel lines like slickensides which will be described presently; and lastly, there is a slight development of sericitic mica along many of the cleaved surfaces. No less important is the alteration produced on the overlying Archæan gneiss. In the heart of the mass, as already stated, there is little apparent change, but near the thrust-plane the beds are drawn in towards it till their strike roughly coincides with that of the thrust-plane. The inclosed hornblende merges into a green chloritoid product, the hornblendic gneiss has been converted into a fine green schistose rock, while the quartz and feldspar of the pegmatites have been drawn out into streaky or wavy lines, so as to assume somewhat the appearance of rhyolites. Finally a new set of divisional planes has been superinduced on the mass, the strike of which is parallel with that of the plane of thrust.

Again, there is clear evidence to show that the thrust-plane just described was followed by minor movements of a similar nature in the gneiss itself, whereby different portions of the mass were made to slip over each other. Occasionally a thin lenticular mass of the bottom-quartzite has been caught in these planes of disruption.

But all these evidences of displacement are merely the precursors of a still more powerful thrust-plane, which has been traced continuously from the shore east of Whitten Head to the crest of Crag-na-Faolinn, and at intervals for many miles to the southward into the Assynt country. The strike of the strata overlying this plane is, on the whole, north-north-east and south-south-west, with a general east-south-easterly dip, usually at comparatively low angles. Though roughly parallel with it, this greater thrust-plane here and there overrides the lower or more westerly one, for the rocks on its upper side may be seen to pass across all the zones of the Silurian series up to the limestones. A recognisable and tolerably persistent order of succession has been observed in the rocks on the upper side of this thrust-plane. At the base, and resting on different platforms, there usually lies a belt of striped fissile schist, followed by green schist with alternations of gneiss, which, though it has lost nearly all trace of its original foliation, is probably a portion of the Archæan gneiss. A number of lenticular masses of Silurian quartzite occur on this horizon between the Whitten Head coast and Crag-na-Faolinn. In some cases, the basal breccia and portions of the overlying false-bedded grits are clearly seen resting on the Archæan rock, the planes of foliation of the gneiss being roughly parallel with the bedding of the quartzites. On closer examination, however, it is observable that successive folia of the gneiss impinge against the basal breccia. In other cases, wedges of the false-bedded grits, without the basal breccia, are caught between two thrust-planes. Perhaps the most remarkable example of these isolated masses of Silurian rocks, is the limestone intercalated among the green schists, on the hill-slope above Eriboll House. This mass appears to belong to one of the higher limestones of the Durness Basin which have not elsewhere been noticed in the Eriboll area. It lies not far above the great thrust-plane, and though its relations to the schists are not as well shown as could be desired, its presence here is evidently due to the same series of movements that brought in the intercalations of quartzite. Passing eastwards we find, next in order, a belt of frilled green schists (No. 8 in Section) with a well-marked calcareous zone near the top, which has been traced from the shore east of Whitten Head for a distance of ten miles in a south-west direction, and which extends still further to the south. To these succeed a thin band of compact siliceous schists (No. 9 in Section) overlain by hornblendic and micaceous gneiss, which is succeeded by a great development of gneissoid flagstones (No. 10) with occasional bands of hornblendic and micaceous garnetiferous schists.

This order of succession in the rocks above the upper thrust-plane is also recognisable far to the west in Sangomore Bay and on Farrid Head in the Durness area. It is evident that there has been an extraordinary amount of movement of these rocks along the upper thrust-plane, since they override all the other rocks pushed forward by the lower thrust-planes in the Eriboll area, and rest directly on the limestones of the Durness Basin. The thin band of shattery quartzite between the striped fissile schist and the limestone in Sangomore Bay is a fragment of the false-bedded quartzite zone which has been pushed forward along the surface of the thrust-plane,—a characteristic feature of the thrust-planes in Eriboll.

The microscopic characters of the rocks from the different zones above the upper thrust-plane have yet to be studied. Much fresh light may thence be expected on the *modus operandi* of the processes involved in the extraordinary lithological changes which the rocks have undergone. Meanwhile a careful examination of the various masses in the field points very clearly to the nature of these processes. The striped green fissile schist which occurs along the thrust-plane presents an exceedingly compact texture with a remarkable streaked structure which at once recalls the fluxion-lines of an eruptive rock. Still more conspicuously is this structure displayed by the masses of pegmatite in the gneiss; they lose their ordinary character and assume more that of rhyolite. The intercalations of quartzite are marked likewise by the same streaked appearance, their component particles of quartz and feldspar being all elongated in one common direction. The gneiss associated with the schists above the thrust-plane, though its original foliation can still in places be detected, has had a new set of schistose planes superinduced in it which are on the whole parallel with the thrust-plane. Bands of hornblendic gneiss merge into hornblende-schist and chlorite-schist, and these again into finely-frilled schists. All these new structures, which are quite independent of the original bedding or foliation of the rocks, were obviously connected with the production of the great thrust-plane, with which they lie more or less parallel. They point to

enormous mechanical movements under which, as the rocks sheared, the individual particles were forced over each other in one common direction, viz. from east-south-east to west-north-west. Further evidence of this mechanical movement is supplied by certain abundant fine parallel lines, like those of slickensides, which occur almost everywhere on the foliation-surfaces or other parallel divisional planes. They are especially well developed among the striped fissile schists and the gneissose flag-stones. These lines run in the same general direction already mentioned (E.S.E. to W.N.W.). In many cases it may be observed that the component particles of the rocks are oriented in this same direction, while original quartz-veins are drawn out into parallel rods. Another important feature connected with these rocks is the development of minerals along the new planes of schistosity. In particular, the abundance of sericite mica is noteworthy, the longer axes of the crystals of which lie in a direction parallel with the slickenside-lines. Other micas, hornblende, actinolite, and garnets have also made their appearance along the same planes. This re-crystallisation becomes more pronounced the further east one advances from the outcrop, or passes upwards from the great thrust-plane.

This accumulated evidence points to the conclusion that in the north-west of Sutherland the rocks have been powerfully affected by one grand series of terrestrial movements whereby new structures have been super-induced upon them. Among these changes the original characters of the rocks have been more or less completely effaced, and new crystalline structures have been produced. Although a normal upward succession from the Silurian strata into an overlying series of schists cannot be maintained in the north of Sutherland, it is nevertheless certain that the displacements and metamorphism here described are later than Lower Silurian time. It is also evident that these great changes had been completed before the time of the Lower Old Red Sandstone, the conglomerates and breccias of which rest upon and are made up of fragments of the crystalline schists.

One final feature of the Durness and Eriboll area remains to be noticed. The geological structure of this region has been further complicated by the subsequent folding of the strata, and by a double system of normal faults (*ff* in Section) which affect the strata and thrust-planes alike. One set of normal faults trends north-north-east and south-south-west, while another, which appears to be newer, trends more or less at right angles to these. By these two systems of later dislocations, the thrust-planes with their low hade have been intersected and shifted precisely as if they had been ordinary boundary-planes between two geological formations. Much of the difficulty, indeed, which has been from the first experienced in unravelling the complicated structure of this region may be traced to the effect of the intricate network of reversed and normal faulting. The very preservation of the Durness Basin is due to two normal step-faults, one of which lets down the quartzites more than 1200 feet, while the other brings the whole Silurian Basin down to the sea-level.

JOHN HORNE

THE GENESIS OF AN IDEA, OR STORY OF A DISCOVERY RELATING TO EQUATIONS IN MULTIPLE QUANTITY

I VENTURE, even at the risk of appearing egoistical, to call the attention of a wider circle of English mathematical readers than are likely to notice it in the pages of the *Comptes Rendus*, to what appears to me a remarkable discovery in the theory of matrices, or, in other words, of multiple quantity which has lately presented itself to me. It seems to me the more necessary to do so because the nature of the theorem which constitutes the discovery would hardly be suspected from the leading title of the note in the *Comptes Rendus* in which it is contained, being indeed an after-thought, so that the sting of the paper has to be sought for in its tail.

Hamilton, of immortal memory, has given, in his "Lectures on Quaternions," a solution of a certain quadratic equation in *quaternions*, those algebraical entities which (building upon a suggestion in Prof. Cayley's ever-memorable paper[1] on matrices, in the *Philosophical Transactions* for 1858 or thereabouts) I have, with the general concurrence of all who have given attention to the subject, found means of identifying with binary matrices or algebraical quantities of the second order, and thus succeeded in determining the True Place of Quaternions in Nature. Now, what Hamilton has done for an equation of the second degree of quantities of the second order, the theorem in question effects in a much more simple and complete manner for a similar sort of equation of any degree and relating to quantities of any order.

The history of the discovery in question constitutes in itself, it seems to me, an interesting chapter in Heuristic. This is how it came about. Hamilton's equation admits of six solutions or roots, which arrange themselves naturally in three pairs, and stand in immediate, and what we algebraists call rational relation to the three roots of a cubic equation, or rather to the six square roots of those three roots. From this it follows immediately that one single condition must be sufficient to reduce the number of distinct roots of the equation in quaternions or binary matrices from six to four, inasmuch as, when two roots of the cubic referred to become equal, two *pairs* of roots of the original equation must coincide. It naturally therefore became an object of interest to obtain the quantity which, equated to zero, expresses the condition of equality of two roots of this cubic, which of course may be effected by means of a well-known formula for finding the discriminant of a cubic equation; but the quantity so obtained directly from the cubic is of an exceedingly complex form, and leaves the mind entirely unsatisfied as to its true internal composition, just as from a handful of diamond dust it would be impossible to infer the crystalline form which constitutes the true idea, the *raison* or *façon d'être* of the glittering gem.

Again and again my mind reverted fruitlessly to the subject until, on September 28 last, pacing the deck of the splendid Dover and Calais boat, the *Invicta*, under the vivifying and genial rays of a bright and benignant sun, the idea occurred to me that the form to be determined must be subject to satisfy a certain partial differential equation, and without the aid of pen or pencil I succeeded, ere the voyage was half over, in identifying the discriminant of the cubic with that of a biquadratic of the simplest imaginable constitution possible: in technical language, supposing $px^2 + qx + r = 0$ to be the equation in question, I discovered virtually that the desired discriminant is identical with that of the biquadratic form which is the determinant of the binary matrix (or the tensor squared of the quaternion) $px^2 + qx + r$ treated as if x were an ordinary quantity. Starting from this point it was easy to infer all the possible cases of equality which could occur between the six roots; and, more than that, to classify under thirteen classes all the principal cases that could present themselves in the solution of the equation, not merely for the general case when there are six actual and determinate roots, but even for those cases when some of the roots pass off into infinity and become conceptual instead of actual, or else, without passing to infinity, remain actual but contain arbitrary constants.

This more-than-anticipated complete solution of the problem before me was in part suggested by the opening

[1] This paper constitutes a second birth of Algebra, its *avatar* in a new and glorified form. See introduction to "Lectures on Universal Algebra" in the sixth volume of the *American Mathematical Journal*.

lines of a memoir by M. Darboux on the solution of a biquadratic equation in Liouville's journal, with which its eminent author, my colleague in the Institute of France, providentially presented me shortly after my arrival in Paris, and which led me to see that the three pairs of solutions of the Hamiltonian equation must stand in immediate conceptual relation to the three pairs of sides of the complete quadrangle formed by a certain conic related to the form $px^2 + qx + r$ (in fact the determinant of the matrix $pu + qv + rw$) with the fixed conic $v^2 - uw$.

Now comes the turning point, the ἀναγνώρισις of this strange eventful history.

> "There's a Divinity that shapes our ends,
> Rough-hew them how we will." [1]

Seized with a sudden and fortunate attack of bronchitis, which confined me to my bed, and in the access of nocturnal fever which that state induces, my thoughts reverted with increased activity to this geometrical figure. It became clear to my inner sense that there ought to be an immediate relation between the biquadratic determinant of the form $px^2 + qx + r$, spoken of above, and the three pairs of its roots, and seizing my courage with both hands, I made bold to declare to myself that the functional parts of the six *identical equations* to the six roots ought to be the three pairs of conjugate quadratic factors of the biquadratic in question.

But if this should turn out to be true, it became impossible not to suspect, or even more than half believe, that an analogous statement must admit of being made for a unilateral equation (*i.e.* one in which, as in Hamilton's, the multipliers of each power of the unknown matrix x lie all on the same side (whether to the right or left) of it) whatever might be the degree of the equation, and whatever the order of the matrices concerned. In other words, supposing $fx = 0$ to be such equation, and $\phi x = 0$ to be the identical equation to any one of its roots, ϕx ought to be contained as an algebraical factor in the determinant of the matrix fx when, for the moment, x therein is regarded as an ordinary quantity. If this were so, then the reciprocal theorem would necessarily be true (on account of the determinant referred to being in general irreducible), viz. that, supposing ω to be the order of the matrices concerned, every algebraical divisor of it, say ϕx, of the degree ω, must be the identically-zero function to one or the other of the matrices x which satisfy the equation $fx = 0$, and consequently it would be only necessary to combine, according to a well-known method of elimination, the given form fx with each in succession of the derived forms, which constitute a brood or litter as it were, issuing "de son propre sein," to obtain all the roots of fx by solving the ordinary algebraical equation det. $(fx) = 0$, and that thus the solution of the unilateral equation would depend on the solution of an ordinary equation of the degree $n\omega$, n being the degree of f in x, and ω the order of the matrices concerned: the number of the roots of fx would therefore be the number of ways of combining $n\omega$ things ω and ω together, *i.e.* $\frac{\Pi(n\omega)}{\Pi\omega\,\Pi(n-1)\omega}$. But herein arose a self-created difficulty, a phantasmal projection of my own brain, to block up the way, and throw doubt and discredit on all that precedes. Supposing $\omega = 2$, the number of roots thus ascertained would be $\frac{2n(2n-1)}{2}$, or $2n^2 - n$, and for $n = 3$ would be 15. Now, in the *London and Edinburgh Philosophical Magazine* for May last, whilst I had shown that $2n^2 - n$ is the number of roots of a unilateral equation in quaternions of the degree n, and of the trinomial or Jerrardian form, I thought I had proved the number of solutions of a *complete* cubic equation in quaternions to be 21 (upon which I based the formula $n(n^2 - n + 1)$ for a unilateral equation of quaternions of the degree n. There was then the choice to be made —to abandon the conjectural theorem, or to admit an error in the supposed determination of the number 21. I felt no hesitation in making my election, especially as there was a loop-hole for error in such numerical determination, inasmuch as no actual arithmetical calculations had been made, but the order of a certain system of equations which ought to be equal to the number of roots of fx was inferred from calculations in which all numerical quantities were left in blank; it was therefore quite possible (however unexpected the fact) that some of the leading coefficients of the resolving equation of the degree 21 might become zero,[1] and consequently that the order might fall below (although it could not rise above) that number. To my gratified surprise my faith met with its reward, for I soon found an easy proof of the remarkable theorem which I have ventured, in emulation of a phrase of Cauchy, to call a "*pulcherrima regula*," which will appear in the number of the *Comptes Rendus* next forthcoming after this date, and which may be summed up approximately in the following words:—*Every latent root of every root of a given unilateral function in matrices of any order, is an algebraical root of the determinant of that function taken as if the unknown were an ordinary quantity, and conversely every algebraical root of the determinant so taken is a latent root of one of the roots of the given function.*[2] This constitutes a marvellous extension (to a matrix implicitly given by a unilateral equation) of the already no-little-marvellous Hamilton-Cayley theorem of the identical equation to a matrix given explicitly.

My good genius met me on the deck of the *Invicta*, and only left me three weeks later on board the returning steamer from Boulogne. There my pleasing algebraical dream came to an end.[3] J. J. SYLVESTER

New College, Oxford, October 26

[1] It is one of Descartes' "self-evident primary truths" that nothing which has happened could not have happened otherwise.

OUR FUTURE WATCHES AND CLOCKS

HOWEVER long the use of the letters "a.m." and "p.m." for distinguishing the two halves of the civil day may survive, it seems probable that the more rational method of counting the hours of the day continuously from midnight through twenty-four hours to the midnight following may before long come into use for a variety of purposes for which it is well adapted, even if it should not yet be generally employed. It seems proper, therefore, to consider in what way ordinary watches and clocks could be best accommodated to such a change in the mode of reckoning. To place twenty-four hours on one circle round the dial instead of twelve hours as at present seems the most natural change to make; but, in addition to a new dial, it would involve also some alteration in construction, since the hour hand would have to make one revolution only in the twenty-four hours instead of two. And there would be this further disadvantage, that the hours being more crowded together, the angular motion of the hand in moving through the space corresponding to one hour would be less—in fact, one-half of its present amount. It is to be remembered that, in taking time from a clock, persons probably pay small attention to the figures, either those for hours

[1] Or else that its functional part might be composite and throw off an irrelevant factor.

[2] In terms more precise as regards the *converse* the theorem runs as follows:—*The identically-zero function to a root of* fx *is a factor of the determinant to* fx, *and conversely every factor of that determinant of degree equal to the order of* x *is identically zero.*

[3] A letter just received from M. Hermite informs me that M. Poincarré, in a paper presented by him to the Institute on Monday last, takes up the wondrous tale of multiple quantity so largely treated of by me in recent articles in the *Comptes Rendus*. The subject could not be in better hands. The ball is served, and the most skilful and practised players—the Cayleys, the Lipschitzes, the Poincarrés, the Weyrs, the Buckheims (and who knows how many more?)—stand round ready to receive it, and keep it flying in the air.—November 8.

or minutes, the relative position of the hands on the dial probably at once sufficiently indicating the time to most persons without any need of reference thereto, but it would be by no means so easy to pick up the hour from a circle containing twenty-four, and especially in the case of public and turret clocks. There is also the question of change of the motion-work to which allusion has been already made—necessary if the hour-hand is to make one revolution only in twenty-four hours—a practical question in regard to which the watch- or clock-maker could probably best speak.

There is another way of adapting ordinary watches and clocks to the twenty-four hour system, which, if the watch is intended only for the reckoning of local time, seems deserving of consideration. It consists in making the hour figures shorter, not necessarily at all less distinct, and placing two circles of figures round the dial, an inner circle with hours from 0 to 11, and an outer circle with hours from 12 to 23. The hour-hand would thus point to 1 and 13 and to 2 and 14, &c., at the same time, it being understood that the hours 0, 1, 2, &c., would be reckoned in the morning, and the hours 12, 13, 14, &c., in the afternoon, a convention to which people would probably soon accommodate themselves. On such a plan a watch would only require a new dial, no change of wheelwork being necessary, so that it could be very readily applied to existing watches, and so sooner promote the use of the twenty-four hour system. Persons might perhaps object to the introduction of two hour-circles from an artistic point of view. But, after all is said, the question whether one circle containing twenty-four hours, or two circles having twelve hours in each, be preferable, is one to be settled only by a consideration of the relative advantages and disadvantages of the two proposals, in regard to which it would be interesting to learn what business men and others on the one hand, and practical watchmakers on the other, may have to say. There are conditions under which the one circle of twenty-four hours would certainly be the more advantageous, and clearly it would be well that one system only should if possible be used.

As regards clocks, there is the further question of striking the hours. For public clocks we could not go on to twenty-four. It may be a question whether in large towns one stroke only at each hour might not be a sufficient indication, though even this rule probably could hardly be universally applied.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

At a meeting of the General Committee of the British Association held at the Royal Institution on the 11th instant, Sir Lyon Playfair was elected President for the meeting at Aberdeen next year. It was resolved to request the following to accept the office of Vice-President for that meeting:—The Duke of Argyll, the Duke of Richmond and Gordon, the Earl of Aberdeen, the Earl of Crawford and Balcarres, Sir William Thomson, James Matthews, Lord Provost of Aberdeen, Dr. Alexander Bain, Lord Rector of the University of Aberdeen, the Very Rev. Principal Pirie, and Prof. W. H. Flower. The following were elected Local Secretaries: Prof. G. Pirie, Dr. Angus Fraser, and Mr. J. W. Crombie; Local Treasurers: Messrs. Robert Lumsden and John Findlater. The following appointments were also made:—General Treasurer: Prof. A. W. Williamson, Ph.D., F.R.S.; General Secretaries: Capt. Douglas Galton, C.B., F.R.S., and A. G. Vernon Harcourt, F.R.S.; Secretary: Prof. Bonney, D.Sc., F.R.S.; Ordinary Members of the Council: Capt. W. de W. Abney, Prof. W. G. Adams, Prof. R. S. Ball, J. F. La Trobe Bateman, Sir F. J. Bramwell, Prof. W. Boyd Dawkins, Dr. Warren De La Rue, Prof. J. Dewar, Capt. Sir F. J. Evans, Prof. W. H. Flower, Dr. J. H. Gladstone, J. W. L. Glaisher, Lieut.-Col. H. H. Godwin-Austen, J. Clarke Hawkshaw, Prof. O. Henrici, Prof. T McK. Hughes, Dr. J. Gwyn Jeffreys, Prof. H. N. Moseley, Admiral Sir E. Ommanney, W. Pengelly, Dr. W. H. Perkin, Prof. Prestwich, the Right Hon. George Sclater-Booth, Dr. H. C. Sorby, Sir R. Temple; Auditors: John Evans, D.C.L., Treas.R.S., Dr. Huggins, F.R.S., and George Griffith, M.A.

Invitations for the year 1886 were received from Birmingham, Bournemouth, and Manchester, and after a discussion (in which the representatives of Manchester expressed their willingness to withdraw in favour of Birmingham for the year 1886, but their earnest hope that the Association would not fail to visit them in 1887), it was agreed, *nem con.*, to accept the invitation from the town of Birmingham for the year 1886.

The report of the Council relating to the rules concerning the representation of local scientific societies at the meetings of the Association and the establishment of a Permanent Committee as a means of union between them and the Association were sanctioned, and it was resolved in accordance with a recommendation from the Council to present the die for the medal which is about to be founded at McGill University, Montreal, in commemoration of the visit of the Association to Montreal.

THE NEW VOLCANIC ISLAND OFF ICELAND

At the end of July this year the light-keeper at Cape Reykjanes, the south-west point of Iceland, reported that a volcanic island had risen in the sea a few miles off the cape. Reykjanes has long been noted as a centre of volcanic activity, and from time to time islands have arisen and submarine eruptions have occurred in its neighbourhood. In the year of the great Skaptárfell eruption, which proved so fatal to Iceland, 1783, an island appeared off Reykjanes, only to disappear again after a very brief existence. Only a year or two ago an eruption of considerable violence occurred in the sea, not far from the spot where the new island appeared. Columns of steam and clouds of dust, mingled with occasional glowing masses of fused rock, were seen to rise out of the sea, and large quantities of pumice were thrown up and drifted ashore on the neighbouring coast.

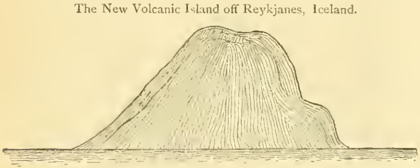
Being desirous to learn as much as possible about the new island, I visited Reykjanes on September 9. The cape, like the greater part of the surrounding district, is entirely covered with lava; not far from the sea lie a number of boiling pools of considerable size, from whose agitated muddy waters arise the columns of steam that give the cape its name, Reykjanes (Smoking Cape); over a large area surrounding the pools the earth is perforated by steam jets and small mud boilers, and the traveller must pass warily over its treacherous surface, for under the thin and yielding upper crust lie beds of soft many-coloured clays, boiling hot, permeated by steam and mixed with sulphur. On a projecting cliff about 150 feet high stands the lighthouse, a low octagonal stone house, and from the point a line of islands, four in number, runs out to the south-west, the nearest being about seven miles, and the farthest about sixteen miles, from the cape. Of these only the nearest two, Eldey or Melsækken (the Meal-sack, so called from the guano deposits that whiten the top of its bleak cylindrical mass), and Eldeyjardrangur, are usually visible from the lighthouse. The farther two, Geirfuglasker and Geirfugladrangur, are chiefly interesting as having been formerly frequented by the Great Auk or Gare-fowl (*Alca impennis*), now apparently extinct.

When I reached Reykjanes, rain and mist obscured the sea, Eldey could only with difficulty be seen, and the new island was quite invisible. I waited patiently for better weather, employing the time in examining the boiling springs and hot clay-beds, which are similar to

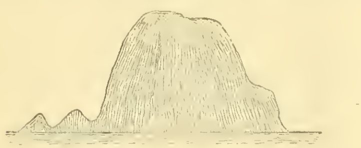
those of the Krísuvík sulphur mines, and the so-called "porcelain rock," a bed of very pure, white, and compact siliceous sinter or geyserite, deposited by some long extinct boiling spring. It was not till the afternoon of the next day that the weather cleared up a little, and a long and patient watch from the top of a hill behind the lighthouse was at length rewarded by the discovery of a dim spot on the horizon, which close observation through a good telescope showed to be the new island. It was quite invisible to the naked eye, but the light-keeper assured me that he had often seen it in clear weather, without a glass. When first seen, on July 29, its shape was that of a truncated cone with a slight depression on the top, and a considerable hollow half way down the slope on the north side.

On August 5 and 6 a series of violent earthquake shocks occurred, which shook and split the masonry of the lighthouse and damaged the lamps. For several days the new island was obscured by mist and rain, and when it again became visible its shape was considerably altered: a large part of the slope on the south side had slipped down into the sea, where it now lies, forming two little hillocks close to the foot of the main mass, and leaving a steep face nearly perpendicular towards the bottom. On the north side there is shoal water extending some distance from the island. The length of the island is about one-third greater than its height. It lies nearly west-south-west of Reykjanes, and considerably to the north-west of Eldey. Two French naval officers who visited Reykjanes and made observations of the island about a fortnight before I arrived there, estimate its distance from the coast at nine or ten miles, but I believe it to be considerably greater. When first seen the island was perfectly black, but now the light-keeper tells me he can in clear weather distinguish by the aid of his glass a perceptible whitening of the upper part, due no doubt to the droppings of the myriads of sea-fowl which frequent the neighbouring islands and coast, and have apparently at once taken possession of the new island.

The New Volcanic Island off Reykjanes, Iceland.



The island as when first seen.



The island as it now appears.

It is a singular fact that none of the usual volcanic manifestations seem to have announced or accompanied the rise of the new island; no earthquakes were felt, no smoke or fire seen, and no pumice found floating on the sea. The island seems to have risen calmly and silently, without a soul being aware of its appearance, till, on July 29, the light-keeper happening to look out to seaward, discovered it. For aught that any one knows to the contrary, it may have been there for many days before he happened to see it. No one has yet visited the island itself; the sea off Rekjanes is almost always rough, and the currents are very strong round the cape; the islands are surrounded by shoals and reefs; landing is at all times difficult and dangerous, even in the best weather, and quite impossible if the sea is at all disturbed; and as, since the discovery of the island, the weather has been for the most part stormy, intending explorers have been deterred by the dangers of the passage. Singularly enough, a French war-vessel and a Danish gun-boat which passed Reykjanes shortly before my visit failed to see the new island. From the direction in which the new island lies, and its apparent distance from the coast, I am inclined to think that it must lie near to the Geirfuglasker (Gare-fowl Skerry), one of the four islands above mentioned, which lies somewhat to the north-west of the line formed by the other three, and which, being low and flat, cannot be seen from Reykjanes. It is not impossible that the new island is merely an addition to or upheaval of the old Geirfuglasker, which, by heightening it so as to make it visible from the shore, would produce the impression that a new island had risen. This view is held by some of the fishermen on the coast who are familiar with the islands, but the point cannot be definitely settled till the island is visited.

W. G. SPENCE PATERSON,
H.B.M. Consul for Iceland

British Consulate, Reykjavík, September 27

TELESCOPES FOR ASTRONOMICAL PHOTOGRAPHY

I.

BEFORE giving any suggestions as to the best kind of telescope to use, and the best methods to follow in the application of photography to astronomical observation and record, it may be more convenient to mention briefly what can be done in this way, particularly as the subject will be new to many who have not followed closely what has been recently done.

I wish to mention (1) That photography has now shown itself to be capable of giving us pictures of nebulæ that are superior to those made by eye and hand. (2) That anything that can be seen by the eye with a telescope of a certain size can be photographed, and, further than this, stars that are too faint to be seen in this telescope can yet be photographed by it with sufficient exposure. (3) That portions of the heavens of several degrees extent each way can be photographed, and stars therein of a magnitude smaller than that shown on the best existing charts or maps, pictured in their proper relative positions and magnitudes in a quicker, better, and more accurate manner than by the plan hitherto used. (4) That it is possible thus to make a complete series of such pictures embracing the whole heavens, that will be practically free from human error. (5) That each individual nebula, cluster, or group of stars, can also be taken on as large a scale as possible, and form a supplement to the picture-maps on the smaller scale. (6) That though such pictures may differ slightly from the eye observations, owing to the different colours of light not affecting the eye and the sensitive plate in the same manner, they would have the enormous advantage that they could be compared directly with other pictures, taken, after the lapse of any number of years, under conditions that there would be no difficulty in making almost identical. (7) That there are other applications of this new power, as in direct enlargements of the surface of the moon piece by piece, of the planets, of double stars, and close clusters, and indirectly in the discovery of planets, either major or minor, by the simple process of direct comparison of star pictures taken at intervals, when the actual position of a planet will be recorded at each date. If there be a planet beyond Neptune, such a plan as this is perhaps the only way to detect it, especially if it is now near the Milky Way, where stars of its probable magnitude cluster so thickly that no process other than this could be used to chart the stars and detect movement. If these things can be done, and I most

confidently say they can, then it must be admitted that nothing short of a revolution in observational astronomy must result, to the enormous gain of astronomy.

I speak relying entirely on my own work and experiments, which I shall refer to in detail further on, and I am strengthened in my opinions by what I hear has been done in a similar direction elsewhere, though I have not, except in one case, seen any of the actual work done.

The possibilities that are thus opened out really border on the marvellous. As has been already said by some one else, a library may now be made, not of books full of descriptions and figures, the accumulated work of many men working many years, each on his own system, but of pictures written on leaves of glass by the stars themselves.

Such a work will mark an epoch in astronomy, and its value increase as long as astronomers exist. No one can doubt for one moment the importance of such a work, nor the fact that, now it is possible, any delay in doing it will be a direct loss to astronomy. How it is to be done—whether by the slow process of letting it be done by the disjointed efforts of many amateurs of astronomy, or by being properly taken in hand and finished by united effort and proper means in the course of a few years—remains to be seen.

I propose to make some suggestions as to the practical part of this work in the selection of the best kind of telescope and mounting, the methods of working, the work to be done, and some other matters in connection. The most important matter is no doubt the selection of the best instrument to work with: of the two kinds of telescopes now in use, the reflector seems to be the most suitable for this work, though a reservation may be made in favour of the refracting principle where large fields on a small scale are required. Both kinds of telescopes when of moderate dimensions, that is, not more than 18 inches aperture, are so nearly alike as optical instruments that the chief distinction worth noting, neglecting for the present one or two points where they differ, and altogether such points as are rather matters of individual prejudice on the part of the observer than qualities or defects in the instruments, is that of cost, the reflector being very much less expensive to make. It is true that the refractor has been hitherto generally considered the most satisfactory in use, and has been preferred when expense has not been a consideration of importance. I think this may be rather due to the greater care that is bestowed upon the more expensive instrument, both in the making of the object-glass and the mounting, than to any real difference that there is between them. The first cost of the raw material alone differs immensely. For the reflector one disk of glass alone is required, and if it is only properly annealed it need not be optically pure. There is only one surface to work, though it is of importance that this should be properly figured, this is not a difficult matter, yet there is little doubt it has often been very imperfectly done in many so-called reflecting telescopes.

For the refractor two disks of glass are required; they must be optically pure, and their first cost alone is more than is often spent on the reflector, including the mounting. These disks must be wrought on four surfaces to proper curves, and time often spent afterwards in perfecting the object-glass; when this is done, the cost is found to be so great that it is felt to be worth a costly mounting. We cannot then be surprised that the better made and mounted telescope should be chosen, but that does not decide the question, Which is the best optical instrument? Nor can this question be decided definitively, because the images formed by each differ. If we look with a reflector at a bright star, the image is seen as an intensely bright point of light, dazzling to the eye if the telescope is large, and we see rays or coruscations round it of an irregular shape that are never steady. I think this effect is not due to the telescope, but is entirely subjective, and caused by this extremely small point of light exciting only a very small portion of the retina; for by proper precautions the light can be reduced, and these rays and the dazzling effect got rid of. With stars less bright it is not so pronounced, and on planets or objects of sensible magnitude it ceases entirely. The image of such a bright star in the refractor is quite of another kind: it is seen as a small disk of light of *sensible diameter* surrounded by the well-known system of diffraction rings and outstanding colour. This disk of light though small, has a different effect on the retina: it can be seen as a shape, pretty steady and free from too much dazzling glare. It is here that the refractor has such an advantage for micrometrical work, permitting bisections to be made with such precision.

The adjustments of the object-glass are considered more constant than those of the speculum, and though the troubles attending the reflector are much exaggerated, they have existed in the arrangements usually adopted. For certain instruments such as the transit-circle, where the connection between the optical axis and some part of the instrument has to be maintained, the object-glass is superior to the speculum; a tilt of the former that would not have an appreciable effect on the position of the image of a star would in the other displace this image twice the amount of tilt.

Both kinds have certain advantages, according to the use they are put to, and it is really not of much consequence which is the best instrument of this size. It is when we begin to consider the effect of increased size and all its attendant difficulties that the question of the suitability of either for the purpose of photography has to be answered.

With the reflector increase of size means proportionate increase in other qualities, in light-grasping power, in defining, and in separating power. With the refractor the greater absorption of light due to increased thickness reduces the light-grasping power, and definition becomes a matter depending not upon the optician but upon the glass-maker; the correction for colour, which even in theory is approximate only, becomes more difficult, and the defects due to the necessarily imperfect correction become more apparent—and these two facts alone show that as the refracting telescope gains in size it becomes more and more unsuitable for photography.

Moreover, when the aperture of the two kinds of telescopes under consideration is the same, the focal length of one must be something like twice that of the other, and that means that the image is four times less bright, and there does not seem to be any indication that the focal length of refractors can be very much reduced. This is only one part of the question, the next and most important one is that of actual cost or difficulty of construction. In the case of the refractor the preliminary difficulty in getting the lumps of glass out of which the lenses have to be made is so great that the increase of the size beyond 30 inches seems at the present moment very doubtful—they may reach 3-foot, or even 4-foot aperture, but it is most unlikely: the cost alone, good or bad, would be simply enormous, and such a size may be for the present left out of consideration. With the reflector the case is entirely different: from what has been said, it is easy to see that the gain by increase of size is proportionate here, and that only mechanical difficulties have to be met. Mirrors of glass covered or coated with silver for the reflecting surface are now in existence of 3- and 4-foot aperture; larger are in hand, and can be made at a cost absurdly below the cost of even a possible refractor: the only limit that I can see here is that of glass, and the limit in this case stops not at 30 inches, as with the refractor, but at something like 70 inches, and that and nothing else of a constructive character prevents the reflector being made much larger, and size is a great

thing in photography. It is, in the case of eye-observation, a fact that you could positively have a telescope too big for the eye to use, but any increase that is at present possible in the reflector would only add to its photographic power.

The optical arrangements of the reflector are so varied that I propose to treat of them in detail for the purpose of indicating the most suitable. A. AINSLIE COMMON

NOTES

THE following is the list of officers, &c., to be proposed at the anniversary meeting of the Royal Society, December 1, 1884:—President, Prof. Thomas Henry Huxley, LL.D. Treasurer, John Evans, D.C.L., LL.D. Secretaries: Prof. George Gabriel Stokes, M.A., D.C.L., LL.D., Prof. Michael Foster, M.A., M.D. Foreign Secretary, Prof. Alexander William Williamson, LL.D. Other Members of the Council: Capt. W. de Wiveleslie Abney, R.E., William Henry M. Christie, Astronomer-Royal, Prof. George H. Darwin, M.A., F.R.A.S., Warren De La Rue, M.A., D.C.L., Robert Etheridge, F.R.S.E., F.G.S., Sir Frederick J. O. Evans, K.C.B., Prof. William Henry Flower, LL.D., Prof. George Carey Foster, B.A., Sir Joseph D. Hooker, K.C.S.I., Prof. Henry N. Moseley, M.A., F.L.S., Hugo Müller, Ph.D., Capt. Andrew Noble, R.A., C.B., Lord Rayleigh, D.C.L., Prof. J. S. Burdon Sanderson, LL.D., Lieut.-Gen. R. Strachey, R.E., C.S.I., Prof. J. J. Sylvester, M.A., D.C.L., LL.D.

PROF. LIVERSIDGE, of the Sydney University, sends to the local press a suggestive communication in connection with the recent meeting of the British Association in Montreal, and the invitation forwarded by the Victorian Premier to visit Melbourne next year. Feeling how insurmountable for the present are the obstacles to such a visit, the writer proposes what appears to be a very wise alternative. Instead of looking forward to a near visit from the Association, he suggests, as a preliminary step, a federation of the various scientific societies in Australia, Tasmania, and New Zealand into an Australasian Association for the Advancement of Science on the lines of the British Association. A first meeting of the new Association might be held in Sydney on the hundredth anniversary of the colony, which with the combined attractions of an International Exhibition might induce a fair number of scientific visitors from England to take part in the proceedings. After the first meeting gatherings could take place annually, or every two or three years, as might be agreed upon by the members, in various parts of Australasia. The writer concludes with the remark, which few will gainsay, that such an Association would tend greatly to advance the sciences in the colonies, and in many ways materially favour their progress elsewhere.

ACCORDING to *Science*, Prof. E. S. Holden, Director of the Washburn Observatory of the University of Wisconsin, has lately collected all the data available for the discussion of the law of distribution of the fixed stars, so far as this is determinable from the method of star-gauging. The data were collected from a comparison with the results of a series of star-gauges in progress with the 15-inch equatorial of the Washburn Observatory; and they included (1) the 683 previously published gauges of Sir W. Herschel, with the places brought down from 1690 to 1860; (2) the 405 unpublished gauges of Sir W. Herschel, extracted from his observing-books, and generously placed at Prof. Holden's disposal by Lieut.-Col. John Herschel (these also reduced to 1860); (3) 500 counts of stars from the published charts of Dr. C. H. F. Peters; (4) 983 counts of stars from the unpublished charts of Dr. Peters, from the Paris charts as revised by him, and from the unpublished ecliptic charts of Prof. Watson; (5) 856 counts of stars from the unpublished and published charts of Dr. J. Palisa. These, with the data from Sir J. Herschel's 605 southern gauges, and Celoria's *Durchmusterung* of the stars between 0° and + 6°, complete the very valuable collection of data which Prof. Holden has brought together in convenient tabular form, and from which one of his most important conclusions is, that the method of star-gauging must be applied to the study of comparatively small regions, and that the results from these are then to be combined into larger groups. Prof. Holden hopes that these tables may serve the valuable end of finally disposing of the fundamental assumption that the stars are equally scattered in space, and may bring about the study of their distribution on a more general basis.

THE Boston Society of Natural History have adopted a policy with regard to their library which, if generally followed, would make scientific libraries more generally useful. The Society send such books as can be replaced to students in any part of the country. The receivers of course pay the cost of carriage, and, in addition, strangers are required to deposit a sum equal to twice the market-value of the books so lent, as a guarantee against loss.

A BUREAU of scientific information has been formed in Philadelphia, composed of officers and members of the Academy of Science, whose duty shall be the imparting, through correspondence, of precise and definite information upon the different departments of science. The organisation is purely voluntary. The Secretary is Prof. Angelo Heilprin, of the Academy of Science.

THE new buildings of the Central School at Paris were opened last week by M. Rouvier, the new Minister of Commerce and Agriculture. A number of speeches were delivered on the occasion, from which we learn that as many as 5000 French engineers owe their training to this institution since its foundation fifty years ago by the late M. Dumas and others. The object contemplated by the erection of this institution was to check the predominatingly theoretical character of the instruction imparted by the Government schools and to remodel the engineering education in France according to the English standard. About ten years ago the establishment was purchased by the Government, but the teachers have held as closely as possible to the lines on which its teaching was originally laid down.

MR. STANFORD, of Charing Cross, has issued a reprint of the paper on the Ethnology of Egyptian Sudán, contributed by Prof. A. H. Keane to the November number of the *Journal* of the Anthropological Institute. This monograph, which will be welcome to all interested in the eventful drama now in progress in the Nile Valley, contains a summary but comprehensive survey of all the races between Egypt and the Equator, which are grouped in five main divisions: Bantu, Negro, Nubian, Semitic, and Hamitic. Much light is thrown on the obscure relations of these peoples to each other, and a clear picture presented to the reader of the manifold ethnical conditions in those regions. The tabulated schemes of all the Sudánese races with their numerous subdivisions, seem to be very complete, and will help to a better understanding of the reports daily received from the scene of the operations undertaken for the relief of Gen. Gordon and the Egyptian garrisons in the Sudán.

THE first annual meeting of the New England Meteorological Society was held in Boston on the 21st ult. The papers read were:—On rain-gauges, by Mr. Fitzgerald; rainfall maps, by Mr. Davis; weather observers in New England, by Prof. Upton; the establishment of a meteorological station on Blue Hill, Mass., by Mr. Rotch.

WITH reference to our recent note to the effect that Prof. Hugo Gyldén, Director of the Stockholm Observatory, had

accepted a professorship at the Göttingen University, we are informed that the celebrated astronomer will, in consequence of the generous offer made to him by the King of Sweden, remain in his native country.

PROF. F. E. NIPHER finds, according to *Science*, from data taken from Dr. Engelmann's observations at St. Louis, Mo., lasting over a period of forty-seven years, that the duration of maximum rains is inversely proportional to the violence, or that the product of violence into duration is constant. This constant is the amount of water which may fall in a continuous rain, and is, for Dr. Engelmann's series of half a century, about 5 inches. A rain of 5 inches per hour may last one hour. A rain of 4 inches per hour may last an hour and a quarter; and such a rain Dr. Engelmann observed. A rain of $2\frac{1}{2}$ inches per hour may last two hours, and several such rains were observed. A rain of 1 inch per hour may last 5 hours. Each of these cases would be a 5-inch rain. For a longer period of time than fifty years it is likely that greater rains than 5 inches may be observed. The same is to be said if observations are to be taken over a wider area of country. In fact, a rain of 6 inches in three hours occurred near Cuba, Mo., some years since. This would increase the value of the constant from five to six, but otherwise the relation will probably remain unchanged. The importance of this law, *Science* points out, is very great in engineering, where the capacity of sewers, culverts, and bridges must be such as to carry the water. A more general investigation which Prof. Nipher is now making will determine the relation between the violence, duration, and frequency not only of maximum but of all rains. This work, when completed, will enable an engineer to construct the water-ways of bridges of such a capacity that they will probably stand a definite number of years before they are washed away. This number of years will be so determined that the interest on the invested capital during the probable life of the bridge will equal the possible damage when the destructive flood comes which the engineer determines shall destroy his work. The running expense of maintaining the bridge is then the least possible.

IN the October number of the *American Journal of Science* Mr. Lewis discusses the validity of observations on supposed glacial action at eleven points in Pennsylvania south of the terminal moraine, all of which he has visited. He concludes that they are all non-glacial, some being simple water-worn gravels, others being ice-rafted boulders, while the scratches reported in two localities are pronounced to be plant-fossils. The glacial action reported in Virginia needs, it is said, similar re-examination.

THE Meudon balloon made its third trial trip last Saturday. Starting at 12.15 noon, when a slight south-west breeze was blowing, it drifted in the direction of the Boulogne racecourse, and after arriving in the vicinity of that place, a distance of about a mile from its starting-point, obeying the motive power controlling its movement, it retraced its journey and alighted at the place from which it had ascended at one o'clock, having thus taken three-quarters of an hour to finish its trip of two miles altogether, going and coming. It is said, however, that the motive power of the voltaic elements was not quite so efficient as had been anticipated.

AT the last meeting of the Geographical Society of Hamburg, Dr. Sievers gave a short sketch of a journey of a year's duration which he intends making in the Cordilleras of Merida in Venezuela. Geographical investigation has, so far, not touched this region. Humboldt travelled through the eastern part from Cumaná to Carácas, the llanos of Carácas and Calabozo, and the districts in the Upper Orinoco, but he did not visit the Cordillera region of Merida. Later travellers also, including Godazzi, whose work was otherwise thorough, did not reach the place. Dr. Sievers will examine the region geologically, and obtain as many measurements of heights as possible.

THE report of a journey from Seul, the capital of Corea, to Songdo, by Mr. Aston, a consular official in Corea, has been published. The difficulties of travel in the country appear to have been much exaggerated; the people are friendly to strangers, and the discomforts are not greater than in China.

ACCORDING to a telegram from Calcutta, Mr. Griesbach, the geologist with the Afghan Boundary Commission, describes the route between Quetta and the Helmund as presenting features very similar to those in the Pishin valley and Candahar, namely, a system of precipitous, deeply eroded ridges, extending from north and south to north-east and south-west. Extensive post-Tertiary deposits fill the intervening valleys. The south-west extremity of the Ghazarband range is composed of sandstone shales and grits of the Flysch facies of Eocene rocks. A series of low hills and valleys stretch between Canjpai and Nushki, which from their composition appear to be merely continuations of the Kojah Amran range, but near Galiahah the formation is distinctly younger, the epoch being mostly trap-rock, which in places bursts through the Cretaceous limestone overlying it, and locally converts it into white marble.

NOT the least valuable of the many excellent reports published in the course of the year by the Chinese Customs department is that of the medical officers on the health of the various ports at which they are stationed. These gentlemen deal frequently with subjects of wider interest than the sanitary condition and health of certain limited portions of the Chinese Empire. Thus in the last reports, Dr. Macgowan, of Wenchow, gives an account of the cholera epidemic which visited China last year. He states, on the authority of a native author, that Indian or Asiatic cholera first made its appearance in China in 1821, medical tradition attributing its origin to the Straits of Malacca, whence it was brought to Fokhien in a junk. It subsequently spread southward to Canton, and from thence to other provinces. In 1825 a great outbreak occurred at Ch'un-Ching. on the Yangtsze, and thence the disease travelled slowly northward, visiting Corea and Japan, where it became extremely virulent. It has since been endemic in China, sometimes becoming epidemic, occasionally extending over the whole of Eastern Asia, and at other times confining itself to a province or part of a province. Dr. Macgowan states that the native doctors treated the disease as common cholera, and did not cure one in a hundred; and he concludes that Indian cholera in China differs from the common cholera of the country only in its epidemic character, the former being migratory, the latter stationary.

IN the *Archives des Sciences physiques et naturelles*, Prof. Forel of Morges has a paper on the solar corona of the spring of 1884, of which the following is a summary. In Switzerland, in the course of the present year, has been observed an extraordinary optical phenomenon consisting of a reddish corona of large diameter surrounding the disk of the sun, as well as of a reddish tint on the white clouds. This corona has been visible since the beginning of the year, and during the months of July and August it was constantly seen. Visible from high altitudes whenever the sky was clear, it was generally lost lower down, hidden probably by the light from lower layers of dust in the atmosphere. The corona is probably occasioned by dust settling in the higher layers of the atmosphere where they are protected from meteorological variations of the lower layers. This dust would be of uniform dimensions, and of a mean diameter of about 0·003 mm. In the absence of any other explanation, M. Forel refers this phenomenon to the brilliant crepuscular illuminations of last winter, and attributes these

luminous objects to the volcanic dust of the eruption of Krakatoa of August 27, 1883. In *La Nature* M. Tissandier describes the corona as observed in two balloon ascents on October 23 and 24.

M. HENRI MAGET is about to publish in Paris an atlas of the French colonies and foreign possessions. The work, which will consist of twenty-five maps, will be brought out with the assistance of eminent French colonial geographers. The maps will be of large size, in three or four colours, and some of them have obtained a silver medal and a diploma of honour, at the recent Geographical Exhibition at Bar-le-Duc. It will be completed in five parts, the first of which has already appeared. This contains maps of (1) New Caledonia, (2) Central Africa (the Congo and the Gahoon), (3) Tonquin, (4) Madagascar, (5) the Grand Duchy of Luxemburg. The second part will contain maps of Réunion, Tahiti, Guadaloupe, Senegal, and the New Hebrides.

WE have again to welcome the appearance of a new edition (the tenth) of Prof. Morren's most useful "Correspondance botanique." Since the appearance of the ninth edition (in 1881) the list of "gardens, chairs, museums, and botanical reviews and societies throughout the world," including also the addresses of all private working botanists known to the editor, has again undergone considerable enlargement—we hope an indication of a gradual spreading of interest in botanical science.

DR. BRUDENELL CARTER has issued in a separate form his now celebrated letter to the *Times* on "Eyesight and Civilisation" (Macmillan and Co.). He has taken the opportunity to introduce a few explanatory diagrams.

PROF. F. W. PUTMAN has sent to the *Leader* a full account of his recent explorations amongst the so-called Liberty Group of Mounds on the Harness estate, Ohio, first surveyed and described by Squier and Davis in 1840. In their great work on "The Ancient Monuments of the Mississippi Valley" these archæologists describe five small mounds within the great square of twenty-seven acres. Most of these, as well as three others represented on their plan just outside a "gateway" on the east side of the larger forty-acre square have been much reduced by cultivation. All have now been carefully examined, two—evidently burial-places—yielding objects of considerable interest. The human bones were much decayed; but amongst the other finds were copper plates, ear-rings, and celts, slate and stone ornaments, some large beads covered with copper, and in one instance with silver over the copper, and many other objects, all of which have been deposited in the Museum of Cambridge University. In another large mound north of the same spot an extensive bed of ashes and charcoal yielded much pottery, pieces of cut mica, some grass matting with charred seeds, nuts, acorns, and bones. Near the eastern corner of the great square stands the largest mound of the whole group, which in future Reports of the Peabody Museum will be referred to as the "Big Mound of the Liberty Group." It is 160 feet long by 80 to 90 wide, and 13 to 18 high, and appears from the portion so far examined to be a burial-place of a remarkable character. Some 40 feet from the centre, at the northern end, twelve chambers were opened, and yielded charred mats and cloth in which the bodies had evidently been wrapped, besides various burnt objects, such as copper plates, ear-rings, shell beads, and long flint knives. In two of the chambers skeletons were found stretched at full length, with a copper plate on one of them, the action of which had preserved the structure of a finely-woven piece of cloth. In the other chambers the bodies had been burnt on the spot, as shown by the relative position of the bones and by the fact that in two instances portions of the bodies had fallen beyond the fire, and so escaped burning. Other discoveries made early in the present year in two of the pits by some boys, under the guidance of Mr. Wilson, yielded a great variety of objects which have also been secured for the Peabody Museum. Important links have thus been obtained between the builders of this great mound and neighbouring earth-works in the Scioto Valley and the constructors of the remarkable group on the Turner estate in the Little Miami Valley.

MR. ELLIS, of 90, New Bond Street, has now on exhibition a number of garments, fur-lined and fur-covered, which were used by the German Polar Expeditions of 1882. In both cases the furs were hardly worn at all. The first expedition, which wintered from August 21, 1882, to September 12, 1883, in Kingawa Fjord, Cumberland Gulf, 60° 15′ W. longitude and 60° 36′ N. latitude, and as there was a perfect calm through the winter, the furs were not necessary; similarly the second expedition, which wintered in the island of South Georgia (36° 5′ W. longitude and 54° 32′ S. latitude) from August 21, 1882, until September 5, 1883, found the temperature equally mild. The furs were lent for exhibition by the Imperial German Polar Commission.

THE last census of Roumania gives a total population of 4,424,961, of which 2,276,558 are males, and 2,148,403 are females. According to religious sects there are 4,198,664 orthodox Greeks, 134,168 Jews, 45,152 Roman Catholics, 28,903 Protestants, 8734 Gregorians, 8108 Armenians, and 1323 Mohammedans. The foreign element in the population is composed as follows:—28,128 Austrians, 9525 Greeks, 3658 Germans, 2822 English, 2706 Russians, 2631 Turks, 1142 French, 167 Italians, and 539 of various nationalities—in all 51,138 persons. The urban population numbers only 781,170, while the rural population is 3,643,783.

ON October 16 a mirage was seen at Lindesberg, in Central Sweden. It represented a large town with four-storied houses, a castle, and a lake. The phenomenon was observed for about fifteen minutes.

THE red sun-glows have recently been observed in the far north of Sweden.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus innuus*) from North Africa, an Anubis Baboon (*Cynocephalus anubis*) from West Africa, a Siamese Blue Pie (*Urocissa magnirostris*) from Siam, presented by Mr. R. B. Colom; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. C. M. Courage; six Alexandrine Parrakeets (*Palæornis alexandri*), a Blossom-headed Parrakeet (*Palæornis cynocephalus*), a Banded Parrakeet (*Palæornis fasciatus*), from British Burmah, presented by Mr. Eugene W. Oates, F.Z.S.; two Ring-necked Parrakeets (*Palæornis torquatus*) from India, presented respectively by Mr. W. G. Burrows and Miss Perry; a Weka Rail (*Ocydromus australis*, white var.) from New Zealand, presented by Mr. J. Satchell Studley; a Brown Capuchin (*Cebus fatuellus*) from Guiana, two Pronghorn Antelopes (*Antilocapra americana* ♂ ♀) from North America, deposited; a Great Grey Shrike (*Lanius excubitor*), six Curlews (*Numenius arquata*), British, purchased; a Blue-winged Teal (*Querquedula cyanoptera* ♂) from South America, received in exchange.

VARIATION OF THE ATOMIC WEIGHTS

THE annexed list contains all the elements except a few very little investigated. If the whole numbers in columns are taken to be each the weight of nine atoms in the gaseous state, and a comparison is made with the best determinations of vapour-densities on record, the result is as follows. The first nineteen determinations are Deville and Troost's, and are to be found in *Comptes Rendus*, xlv. (1857) p. 823; lvi. (1863) p. 893; lx. (1865) p. 1222; lxiii. (1866) p. 20.

[1] *Proc. Roy. Soc.* xxvii. p. 427.

[2] *Journ. Chem. Soc.* v. p. 69.

The agreement in all cases is such that, considering the difficulties with which the determination of vapour-densities is attended, it is not likely that other atomic weights could be chosen to obtain like good results. If now the weights in column *t* are taken to be the weights of a single atom for each element in a certain solid or liquid state, the percentages of oxygen in the following chlorates agree closely with the values found by experiment,[1] to wit:—

$100AgClO_6$	contain	25·0525	O	
	found	25·0795	O	Stas
	,,	25·088	O	Marignac
$100AgBrO_6$	contain	20·34	O	
		20·349	O	Stas
$100AgIO_6$	,,	16·9619	O	
		16·9747	O	Stas
		17·047	O	Millon
$100KBrO_6$	,,	28·7307	O	
		28·6755	O	Marignac
$100KIO_6$	,,	22·4227	O	
		22·473	O	Millon
$100NaClO_6$	,,	45·0672	O	
		45·0705	O	Penny

The agreement in these instances is as good as with the adopted weights; but it is complete also in the following cases, in which there are great discrepancies with the prevailing atomic weights:—

$100PtCl_2KCl$ contain	69·362	$PtCl_2$ and	30·638	KCl	
	69·417	,,	30·583	,,	Berzelius
	69·318	,,	30·682	,,	Seubert
Mean	69·3675	,,	30·6325	,,	
,, ,, yield	...	...	... 117·825	AgCl	
			117·9606	,,	Seubert

The agreement of the mean of the percentages of Berzelius and Seubert with the calculated values is complete; the discrepancy between the amounts of silver chloride is small and within the limits of errors of observation. But the percentages of platinum and chlorine in $PtCl_2$ arrived at by the two experimenters are widely different, viz.:—

40·424 Pt; 28·993 Cl Berzelius
40·107 ,, ; 29·211 ,, Seubert

The true weight of the chlorine follows from Seubert's analysis of the ammonium salt—

$100H_4N_3PtCl_3$ yield 194·954 $(AgCl)_3$
Seubert obtained 192·846 ,,

His rate between the silver chloride and the potassium salt gives ... } Pt = 195·002 Clarke
His rate between the silver chloride and the ammonium salt gives ... } ,, = 196·871 ,, ;

the latter rate is therefore at fault, and 100 parts of the ammonium salt correspond to 194·694 AgCl, if the rate is the same as with the potassium salt; the difference between this number and 194·954 is within the limits of errors of observation. The rate $\frac{100}{194·954} \times (AgCl_3)_3$ gives $H_4N_3ClPtCl_2 = 70·84883$, and the rate $\frac{69·362}{30·538} \times KCl$ gives $PtCl_2 = 53·95833$; H_4N_3Cl is therefore 16·8905, and as the weight of H_4N_3 is not in doubt and = 5·74468, Cl is = 11·14583, as in column *t*. With this weight of chlorine all discrepancies disappear, while the weights recalculated from the same data vary between Pt = 194·314 and 196·871. It is moreover minutely confirmed by the results obtained from all the other elements of the same group.

$100OsCl_2KCl$ contain } 41·0226 Os; 28·5027 Cl; 30·4747 KCl
40·638 ,, 28·9024 ,, 30·4596 ,, Berzeliu

Berzelius's percentage of chlorine is again too large, very nearly to the same extent as the chlorine found by him in the potassioplatinum chloride, while the percentage of the potassium chloride is very exact.

[1] The experimental values are those recalculated by Prof. F. W. Clarke ("Smithsonian Miscell. Coll.," vol. xxvii.).

$100IrCl_2N_3H_4Cl$ contain	44·3691 Pt	
	43·732 ,,	Seubert
$100IrCl_2KCl$ contain	40·3874 ,, ; 28·8097 Cl ; 30·803 KCl	
	39·88 ,, 29·291 ,, 30·82 ,,	Seubert
	29 ,,	Berzelius

The same discrepancies as in the case of the platinum salts present themselves: as the percentage of the potassium chloride is exact, that of $IrCl_2$ follows; and, as to the weight of the chlorine, the difference of the percentages found by the two experimenters shows that there is the same cause of error as in the corresponding platinum salt.

$100PdCl_2.2KCl$ contain	32·678 Pd ; 21·4512 Cl ; 45·8708 KCl	
	32·69 ,, 21·416 ,, 45·892 ,,	Berzelius

The agreement is here as good as complete; but the values actually derived from these data vary from Pd = 104·674 to 110·796, owing to the value of the weight assumed for chlorine.

$100Rh.Na_3Cl_3.Cl_3$ contain—

27·1468 Rh ;	45·6215 NaCl ;	27·2317 Cl	
27·094 ,,	45·577 ,,	27·329 ,,	Berzelius

$100Rh.2KCl.Cl_3$ contain—

29·1276 Rh ;	41·6537 KCl ;	29·2187 Cl	
28·989 ,,	41·45 ,,	29·561 ,,	Berzelius

The agreement is almost complete in the case of the sodium salt, and not doubtful in the other, because the weight of KCl is certain. The values for rhodium derived from the sodium salt are very discordant, varying from 102·98 to 105·696.

$100Ru.2KCl.Cl_3$ contain	28·9984 Ru ;	41·7297 KCl ;	29·2719 Cl	
Numbers actually found	28·96 ,,	41·39 ,,		Claus
Mean of the 3 experiments	28·78 ,,	41·09 ,,	30·17 ,,	Claus

The calculated amount of ruthenium is undoubtedly the actual percentage, because 28·91 Ru were found in the second experiment as 28·96 in the first; and the weight of KCl not being doubtful, that of chlorine can only be as calculated. The results which have been derived from these data are most discordant, viz. Ru 96·854—107·19.

The weights of column *s* give $O_6 = 16$ and $S_3 = 16$; those of column *t*, $O_6 = 15·31914$, $S_3 = 15$. . . . There is consequently a difference of the chemical proportions in the two states which explains many anomalies encountered in analytical work, and among others the following:—Berzelius observes (*Pogg. Ann.* viii. p. 16) that, from causes which he has been unable to discover, the atomic weight of sulphur cannot be derived from the specific gravities of the gaseous compounds H_2S and SO_2, the numbers obtained being so high that the discrepancies exceed the limits of possible errors of observation. He had obtained S = 201·165 from the analysis of $PbSO_4$; Thénard and Gay-Lussac's weighing of H_2S gave S = 203·9; his own weighing of SO_2, 207·58. His weight for O being 100, these 207·58 S represent 407·58 SO_2, which with $S_3 = O_6$ give S = 203·79, practically the same as the value derived from the other gaseous compound. The two numbers 203·9 and 203·79 reduced to the value of the weights of column *t* give respectively 191·056 and 191·053. Berzelius's number 201·165 corresponds to the value of column *t*, H being = 1; with H = 0·95745, the actual weight, it becomes 192·605. The three numbers in hydrogen units—15·292, 15·284, and 15·408—though from different causes all too large, agree with each other as well as can be expected under the circumstances, and the difficulty disappears therefore with the adoption of the weights of columns *s* and *t* for the two different states.

This being so, it is to be expected that for other states the weights will also be still further different, and this conclusion is fully confirmed by the facts. Let the weights of column *t* be = 1, then the weights of the states *a*, *b*, and *c* are as follows:—

$$a = 0·999104 ;\ b = 0·997338 ;\ c = 0·99468.$$

Instead of such loss of weight there may be a gain to the same extent, as, for instance, in the state $\frac{1}{b} = 1·002662$. There are still other variations which are multiples of *a*, *b*, *c*, as—

$$a^{\frac{3}{2}} = 0·99866 ;\ \frac{c^2a}{2} = 0·99424 ;\ cb = 0·99203.$$

The evidence of the reality of these weights appears from the following comparison with some of the very best experiments on record. The numbers marked with an asterisk are derived by the volumetric method, which, in consequence of variation of the atomic weights, yields in all cases more or less faulty results.

$100KClO_6$ contain ...	60·87379 KCl = 1

These determinations include the most classical labours on record, and the general agreement with the calculated numbers is surprising, and the more conspicuous in the cases in which the efforts of the experimenters to exclude error have been pushed to the utmost limits, as in Stas's syntheses and in Prof. Crookes's synthesis of thallium nitrate. Notwithstanding the difficulty in this case, because the element is the heaviest of all so far discovered, one experiment has yielded the identical calculated number, and the mean of all deviates from it only by 0·00131. Moreover the same weights recur in similar compounds; all nitrates, for instance, have a lower value than the corresponding chlorides and sulphates, and the value is the lower the greater the composition, as in the alums. The evidence is such that no doubt seems to be admissible as to the reality of a variation of the atomic weights. This conclusion is independent of any value of the atomic weights; for the discrepancies exhibited in the results of Prof. Clarke's recalculations from the same experimental data above quoted are inevitable if the variation of the atomic weights is not taken into account. In c units Ag is 108·09679 if $H = 1$, calculated from the weights of column t; Cl in the gaseous state is $= 35·66$; the calculated weights correspond therefore, within the limits of experimental errors, to the atomic, but the weights are those of different states.

The difference between the weights of the gaseous and the other states is very considerable; the weight of 3 molecules of $H_4N_3I . HgI$, for instance, is $= 378$ in the state of gas, 354·734 in t units, 352·847 in units $= c$; the discrepancies are so great that they exceed by far the limits of possible errors, and as from the comparisons made it appears certain that the different values are realities, the only explanation is that the atomic weights vary. If in new experiments, in which the possibility of variation is kept in view, all discrepancies which actually exist should disappear, variation will be established beyond all doubt. It will then be in order to inquire into its cause. How the weights of the table have been obtained is, for the present, unessential; it is only necessary to add that column v contains Prof. Clarke's recalculated weights, and column u the same values calculated from the weights of column t, column x giving the number of atoms represented in each instance. Column w shows the corresponding weights of the gaseous state. These columns have been added for the sake of comparison.

San Francisco, California, July 24 E. VOGEL

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following gentlemen were on Monday, November 3, elected to Fellowships at St. John's College:—C. M. Stewart, M.A., First Class in Natural Sciences Tripos of 1879, author of several papers on chemical subjects, and Master

at the Newcastle School, Staffordshire; J. Brill, B.A., Fourth Wranger in 1882, Assistant Professor of Mathematics in University College, Aberystwith; W. F. R. Weldon, B.A., First Class in the Natural Sciences Tripos of 1881, author of a number of papers in Zoology and Comparative Anatomy, formerly Demonstrator to the Professor of Zoology and in the Morphological Laboratory; A. R. Johnson, B.A., Sixth Wrangler and First Division in the Mathematical Tripos of 1882–83 (new regulations), author of papers in the *Messenger of Mathematics*, &c.; G. F. Stout, B.A., First Class in the Chemical Tripos of 1881–82 (new regulations), and First Class (with distinction in Metaphysics) in the Moral Sciences Tripos of 1883; G. B. Mathews, B.A., Senior Wrangler in 1884, Professor of Mathematics in the University College of North Wales, Bangor. It is worth noting that Pure and Applied Mathematics, Chemistry, and Biology have been markedly recognised by this election.

Dr. Donald MacAlister has been appointed University Lecturer in Medicine, and Dr. Bushell Annington University Lecturer in Medical Jurisprudence.

Mr. Walter Heape has been approved by the Board for Biology and Geology as Demonstrator in Animal Morphology, on the nomination of the Lecturer in that subject, Mr. Sedgwick.

Prof. Sidgwick, Prof. Adamson (Owens College), and Messrs. James Ward and J. S. Nicholson are appointed Examiners for the Moral Sciences Tripos.

Mr. A. R. Forsyth of Trinity College is appointed Examiner in the Mathematical Tripos (Third Part) in January next, in the place of the late Mr. R. C. Rowe.

In reference to our note a fortnight ago (vol. xxx. p. 649), we should state that, at Trinity College, Major Scholarships of the value of 80*l*. a year, which may be raised to 100*l*. subsequently, are open for competition in Natural Sciences as well as in Classics and Mathematics to persons not yet in residence, with the usual restriction as to age.

SHEFFIELD.—Another step has been taken in the formation of the new Engineering School at Firth College, Sheffield, in the appointment of Mr. W. H. Greenwood to be Professor of Metallurgy and Mechanical Engineering, and Mr. Ripper to be Assistant Professor of Engineering. It may be in the memory of our readers that the City and Guilds of London Institute made a grant about eighteen months ago of 300*l*. a year to the Firth College in aid of the establishment of a Chair of Engineering. Since then additional subscriptions have been promised for five years to the amount of 550*l*., together with a capital sum of over 10,000*l*. A site for laboratories and shops has been obtained, and these will be proceeded with as soon as possible. It is hoped that the special advantages of Sheffield will make it the central school of metallurgy, especially for iron and steel, in the kingdom, and the Committee intend to spare no efforts in rendering it a complete and effective one.

SCIENTIFIC SERIALS

The American Journal of Science, September.—On the amount of the atmospheric absorption, by S. P. Langley. From numerous observations taken at sea-level or at an altitude of nearly 15,000 feet, the author is led to infer that the mean absorption of light as well as of heat by our atmosphere is probably at least double the usual estimate of about 20 per cent. He also believes that fine dust particles, both near the surface and at a great altitude, play a more important part in this absorption, both general and selective, than has been hitherto supposed.—A study of tornadoes, by Henry A. Hazen. In this paper the author examines some of the ordinary theories that are advanced for explaining the origin and development of these destructive phenomena. After showing some of the seeming difficulties involved in these theories, he proceeds to point out a few of the characteristics of the outbursts, with a view to opening up fresh lines of investigation, upon which a further advance may be made towards a true knowledge of the forces underlying them. He is inclined to think that J. Allan Broun's theory, attributing tornadoes to the direct influence of the sun's electricity upon the moisture of the air, or possibly to the indirect effect from the sun's heat, is more satisfactory than the numerous theories of friction, evaporation, condensation, sudden changes of temperature, and the like.—On the absorption of radiant heat by carbon dioxide, by J. E. Keeler. The author considers it probable that to the action of CO_2 in the atmosphere is due one or more of the great gaps in the invisible part of the solar spectrum which the discoveries of Prof. Langley show to be much more extensive than had hitherto been supposed. He further regards it as certain that some other agent than this gas contributes essentially to the total absorptive power of the atmosphere, so that a method of analysis based on this power, in which the effect of the second agent is neglected, cannot lead to correct results.—Note on the Triassic insects from Fairplay, Colorado, by Samuel N. Scudder. These fossil remains present an assemblage of forms altogether different from anything hitherto found in the Palæozoic series on the one hand, or in the Jurassic beds on the other. They seem to show a commingling of strict Jurassic forms with a larger proportion of types which may be called Upper Carboniferous or Permian, with a distinct Jurassic leaning. Hence the probability that the beds in which they occur belong to the Triassic or intermediate formation.—On the flexibility of Itacolumite, by Orville A. Derby. From observations made on this extensive series of quartzose rocks occurring in the gold and diamond regions of Minas Geraes, Brazil, the author infers that the peculiar property of flexibility attributed to them is not an original characteristic, but only a surface character, a phase of weathering or decay brought about by percolating waters.—On the age of the glazed and contorted slaty rocks in the vicinity of Schodack Landing, Rensselaer County, New York, by S. W. Ford.—On the relations of the mineral belts of the Pacific slope to the great upheavals, by Geo. F. Becker. The views of H. P. Blake and Clarence King regarding the parallelism of the series of mineral belts on the Pacific slope to the great mountain ranges, and attributing the deposits themselves to the solfateric action accompanying the ejection of igneous rocks, have since been mainly confirmed. But, independently of any theory, a conclusion of economical importance evidently follows from the fresh facts recently brought to light. A great majority of all the rich ores west of the Wahsatch Range occur in belts following the western edges of distinct geological areas—the Cretaceous in Utah, the Palæozoic and Carboniferous in Nevada and Arizona, the Jura-Trias in East California, &c. Hence analogy points to the neighbourhood of the still unexplored portions of these contacts as the most promising for future discoveries of the precious metals.—Notice of the remarkable marine fauna occupying the outer banks off the southern coast of New England, No. 9, by A. E. Verrill.—Brief contributions to zoology from the Museum of Yale College, No. lv.—Work of the steamer *Albatross* in 1883.—Geology of the Blue Ridge, near Balcony Falls, Virginia, by John L. Campbell.

October.—On the duration of colour-impressions upon the retina, by Edward L. Nichols. Taking up the subject where it was left fifty years ago by Plateau's researches, the author concludes, from a protracted series of experiments: (1) that the study of the duration of colour-impressions produced by different portions of the spectrum tends to confirm Plateau's results; (2) that the persistence of the image is a function of the wave-length producing it, being greatest at the ends of the spectrum, and least in the yellow; (3) that it decreases with the intensity of the ray producing it; (4) that it is not the same for all eyes; (5) that the duration is in inverse order to the luminosity of the colours producing it; (6) that each wave-length of the visible spectrum produces three primary impressions, red, green, and violet, of which the green is the most evanescent, violet the most persistent; (7) that the duration of the retinal image depends upon the length of time during which the eye has been exposed, decreasing as the exposure increases.—Description of a fulgurite from Mount Thielson, Oregon (one illustration), by J. S. Diller.—On the paramorphosis of pyroxene to hornblende in rocks (two illustrations), by Geo. H. Williams.—On the southward ending of a great synclinal in the Taconic Range (with a map and several illustrations), by James D. Dana. The section of the Taconic Range here dealt with extends about 150 miles along the western border of New England, mainly between Middlebury, in Central Vermont, and Salisbury, in North-Western Connecticut. The conclusions arrived at regarding the synclinal character of the system and the Lower Silurian age of the rocks agree with those of Sir William Logan, except that he made the limestone to precede instead of to include the Trenton group.—On supposed glaciation in Pennsylvania, south of the terminal moraine (with a map), by Prof. H. Carville Lewis. The author considers that all the existing surface phenomena may be explained by the action of running waters and other causes independent of glaciation.—History and chemical analysis of a mass of meteoric iron

found in a head-stream of the Red River, Wichita County, Texas, by J. W. Mallet. The analysis yielded iron over 90 per cent., nickel over 8, a little cobalt, tin, phosphorus, copper, sulphur, graphitic carbon, silica, and a trace of manganese.—The life and work of Jean-Baptiste-André Dumas, by J. P. Cooke.—Account of a new meteorite discovered in Grand Rapids, Michigan, on May 15, 1883, by J. R. Eastman. The analysis of the fragment now in the Smithsonian Institute yielded: iron 94·543, nickel 3·815, cobalt 0·369, insoluble residue 0·118.

Rivista Scientifico-Industriale, September 15-30.—Origin of atmospheric electricity, of thunder-clouds and volcanic eruptions, by Giovanni Luvini.—Description of an automatic and continuous registrator of electric energy transmitted at a given part of a circuit, by Prof. Rinaldo Ferrini.—On the electric conductivity of greatly diluted saline solutions, by Dr. Giuseppe Vicentini.—On a system of electro-chronometric bells adapted to private residences, by Giuseppe Bianchedi.—Note on the Walker railway-carriage break, by Angiolo Villa.—On a new system of simultaneous telegraphy and telephony, by M. Van Rysselberghe.—Descriptive notes on the fauna of Sardinia, by Prof. A. Costa.

SOCIETIES AND ACADEMIES

London

Chemical Society, November 6.—Dr. Perkin, F.R.S., President, in the chair.—It was announced that a ballot for the election of Fellows would take place at the next meeting of the Society (November 20).—The following papers were read:—On the action of aldehydes and ammonia upon benzil (continued), by F. R. Japp and S. C. Hooker. In previous papers two general reactions have been studied relating to the joint action of aldehydes and ammonia upon similar bodies; in addition, a third totally distinct reaction occurs, which is investigated in the present paper. The authors have studied the action of salicylaldehyde and ammonia upon benzil. A condensation-product, $C_{28}H_{24}N_2O_4$, was obtained, which proved to be dibenzoyldihydroxystilbenediamine. By the action of dilute hydrochloric acid, the hydrochloride of a new base, $C_{14}H_{16}N_2O_2$, was formed; its platinum salt, picrate, sulphate, diacetyl derivative, &c., were prepared and examined. The authors have also studied the action of furfuraldehyde and ammonia upon benzil.—Isomeric modifications of sodium sulphate, by S. U. Pickering. The author has determined the heat of dissolution of effloresced sodium sulphate heated to various temperatures. He concludes that there are two modifications: one formed by not heating above 150°, the other being produced at temperatures from 150° to the fusing-point of the salt.—On some vanadates of the amines, by G. H. Bailey. The author has prepared and studied a considerable number of these bodies, and has compared them with the corresponding vanadates of the alkalies—Contributions to our knowledge of acetoacetic ether, part 1, by J. W. James.—On magnesium hydrosulphide solution and its use in chemico-legal cases as a source of hydrogen sulphide, by E. Divers and T. Shimidzu. The authors prepare this solution by passing ordinary hydrogen sulphide into a flask containing magnesia suspended in water. By heating the solution to 60°, a steady stream of hydrogen sulphide free from hydrogen and from hydrogen arsenide is obtained.—On the origin of calcium thiosulphate: an emendatory note to a paper on calcium hydrosulphide, by E. Divers. The author concludes that there is essentially only one method of forming the thiosulphate, *i.e.* by the union of sulphur with calcium sulphite.

Physical Society, November 8.—Prof. Ayrton in the chair.—Mr. Kavargee was elected a member of the Society.—Prof. F. Guthrie read a paper on certain phenomena attending mixture. In a previous paper Dr. Guthrie had noticed the increase of volume attending the separation of triethylamine and water effected by heat. The present paper is an account of a more thorough examination of this and allied phenomena. Experiments conducted with a number of different liquids showed that mixtures can be arranged in two distinct classes. Of the first a mixture of water and ether is an example: when shaken up together they mix, heat is *evolved*, and a *diminution* of bulk takes place. If any excess of ether present is poured off, and the lower clear liquid *heated* in a sealed tube, it becomes turbid owing to the separation of the ether. This is accompanied by an *increase* of bulk and *absorption* of heat. Triethylamine and water and diethylamine and water are mixtures belonging to this class; the temperature of separation is a function of the ratio in which the two liquids are present. A typical case of the second class is a mixture of alcohol and bisulphide of carbon. These mix with one another in all proportions above 0° C. with *increase* of bulk and *absorption* of heat. Upon being *cooled* to about −17° C. they separate. The separation of a mixture of ether and water and of a mixture of alcohol and the bisulphide was shown. In these cases the action is regarded as a chemical one, and generally an excess of one liquid or the other is present. To determine the combining proportions two methods were used. In the first a number of mixtures of the same two liquids in different proprtions were taken, and the rise or fall of temperature produced by their mixture measured. When this was a maximum, there might be assumed to be no "dead matter" present. In the second method, which is more delicate, but more laborious, and which was used when the approximate combining proportion had been found by the first, the change of volume produced by mixture was noted; when this increment is a maximum, the liquids are present in their combining proportion. These experiments gave very concordant and definite results: for example, the molecular compound of ether and carbonic sulphide is represented by the formula $C_4H_{10}O,2CS_2$, and that of chloroform and carbonic sulphide by $CHCl_3,CS_2$. A striking confirmation of this view is afforded by the behaviour of the vapour-tension of a mixture. The temperature being constant, if the vapour-tension is plotted with the percentages of the more volatile liquid as abscissæ, the curve is, for a mixture of two liquids which have no chemical action upon one another, as the iodide and bromide of ethyl, a straight line. For ordinary mixtures, however, this is not the case. A curve is obtained in which there is observable at a certain point an irregularity. The corresponding abscissa indicates the molecular combination found by the previous experiments.—Dr. C. R. Alder Wright read a paper by himself and Mr. C. Thompson, on voltaic and thermo-voltaic constants. In a former paper the authors had stated that in a cell set up with two metals immersed in pure solutions of their corresponding salts, a given increment in the strength of the solution surrounding the metal acquiring the higher potential causes an increment (a) in the E.M.F. set up (e), while an increment in the strength of the other solution causes a decrement (b) in the E.M.F. This law is now substantiated; it is, however, found that for dilute acids, instead of metallic salts, (b) may be negative. The authors also find that it is possible to represent the E.M.F. of a cell by the difference of two quantities which they term the voltaic constants. These are quantities, one relating to each plate and its surrounding liquid. The voltaic constant of a metal and a liquid is a function of the nature of the metal surface, the strength of the solution, and the temperature, but is independent of the opposed plate and its liquid; it is practically defined as the E.M.F. set up when opposed to a zinc plate in a solution of the corresponding salt of the same molecular strength. The authors further conclude that the E.M.F. of a given combination usually *stands in no simple relationship to the chemical action taking place in the cell*, but that it may be expressed by the sum of the mechanical equivalent of the chemical action per electro-chemical equivalent, and the difference of two quantities, one being related to each metal and its surrounding liquid, and being constant for that metal and liquid termed *thermo-voltaic constants*. This thermo-voltaic action may act with or against the chemical action in producing E.M.F. In some cases, as in that of a cell composed of iron in ferrous sulphate and cadmium in cadmic sulphate solutions, the E.M.F. is against and greater than that produced by chemical action; consequently the cell works backwards with absorption of heat. At the close of the paper Prof. Ayrton and Dr. Guthrie remarked upon the apparent exception here shown to the second law of thermodynamics.

Paris

Academy of Sciences, November 3.—M. Rolland, President, in the chair.—Observations of the new planet 244 made on October 22 to 24 with the equatorial *coudé*, with remarks on the efficiency of this instrument, by M. Lœwy. The author gives a full account of the performance of this equatorial, which has now been installed in the Paris Observatory for the last two years. His opinion of its excellent qualities is supported by the testimony of Dr. Gill and Mr. Norman Lockyer, the latter of whom pronounces it one of the instruments of the future.—A first study on the parallax of the sun, by M. Bouquet de la

Grye. This paper is based on the calculations made in Mexico by the author and M. F. Arago during the late transit of Venus. From the measurements then taken there results a mean parallax of 8·76 with an apparent approximation of 1/100 of a second.—Studies made at the Physiological Station on the locomotion of men by means of the odograph, by M. Marey. These studies have been undertaken mainly with a view to practical results. One of the objects has been to determine the most favourable conditions under which military forced marches can be accomplished most rapidly and with the least expenditure of muscular energy. The paper is accompanied by two illustrations, showing the readings of the odograph for a man walking at the rate of sixty paces per minute, and the curves of velocity and of the length of stride under various conditions.—A fresh contribution to the study of the Permian reptiles, by M. A. Gaudry.—Note on complex numbers, analogous to the quaternions of Hamilton, by M. H. Poincaré. The various problems connected with this subject are reduced to the following: to find all the continuous groups of linear substitutions variable to n, whose coefficients are linear functions of n arbitrary parameters. This problem is here dealt with.—On the involution of higher dimensions, by M. N. Vanecek.—On some general properties of algebraic surfaces of any degree, by M. Maurice d'Ocagne.—Note on algebraic equations, by M. Berloty.—On the conditions of equilibrium of a liquid mass subjected to electro-magnetic action, by M. G. Lippmann.—Conditions of a helicoidal element for the maximum of efficiency in a screw propeller, by M. Ch. Hauvel.—A comparison of the weighted thermometer with the tubular thermometer, by M. Em. Barbier. The author presents a fresh proof of the proposition already demonstrated by M. Regnault, that if the two instruments agree at the two fixed points, they remain in agreement at all fixed temperatures.—Description of two portable electric lamps, invented by M. G. Trouvé. The author, who gives two illustrations, describes two types of electric lamp, one suited for domestic purposes, the other for workshops, factories, mines, &c. Superiority over all others is claimed for both, on the ground of lightness, portability, convenience, and absolute security even in the most explosive atmospheres.—On the decomposition of the oxide of copper by heat, by M. E. J. Maumené.—Experimental researches on the temporary preservation of various virulent agents in animal organisms, where they remain in a quiescent state, by M. G. Colin. From these experiments it appears that the virus, in passing to animals where it is harmless, may preserve its properties intact for one or two weeks even under unfavourable conditions. It is also shown that in certain refractory cases the virus may give rise to serious and even fatal disorders without any apparent analogy to those caused by it in normal subjects; and further that the same animals may serve several times at varying intervals for the transmission of the poison, although a first inoculation may not have produced in them the attenuating effects of vaccination.—On the employment of the sulphate of copper for the destruction of mildew, by M. P. de Lafitte.

BERLIN

Physiological Society, October 31.—Herr Aronsohn presented a report of experiments which he had instituted in conjunction with Herr Sachs, and which had led to the discovery of a thermal centre in the cerebrum. Starting with the idea that in consequence of a diabetic prick of the medulla oblongata an increase of temperature would manifest itself in the liver, and finding by experiment no confirmation of this conjecture, Herr Aronsohn pushed his investigations for other thermal centres in the brain, and in the course of these researches came upon a spot where, on wounding it with a needle, a very considerable rise of temperature quickly set in. The speaker was not able to specify more exactly the spot at which it was necessary to make the prick in order to produce this effect. It was at all events certain that it was rather limited, and should be determined by more minute anatomical examinations of a number of brains of animals preserved in chromic acid after being operated on. Equally deep pricks made at every other spot of the cerebrum had either produced no effect on the temperature of the body, or had lowered it somewhat. In all the successful cases the corpus striatum was pierced by the needle; in all the unsuccessful cases the corpus striatum remained untouched. There was yet, however, no warrant from this circumstance to conclude where the exact seat of the thermal centre was situated.—Dr. Rawitz described some observations he had made with reference to the copulation of snails, a subject which had hitherto no been investigated. He further communicated from his own experience that snails (*Helix pomatia* and *hortensis*) could, in a state of captivity, be fed on paper. Dr. Kossel confirmed this statement from his own observations, and related that, on feeding snails with highly calcareous paper, abnormal calcareous deposits were observed in their monstrously developed shells.

VIENNA

Imperial Academy of Sciences, October 9.—Preliminary communication on monocyclic systems, by L. Boltzmann.—On the anatomical process of tabes dorsalis, by A. Adamkiewicz.—On double refraction of light in liquids, by E. von Fleischl.—On the comets recently discovered by Barnard (Nashville) on July 16, and by Wolf (Heidelberg) on September 17, and on their ephemerides and elements as computed by K. Zelbr at the Vienna Observatory, by E. Weiss.—On the development of the walls of arteries, by B. Morpurgo.—On the perception of sound, by E. Bruecke.—On the action of benzoyl-hyperoxide on amylene, by E. Lippmann.

STOCKHOLM

Society of Natural Sciences, October 18.—Prof. Sandahl, President, in the chair.—On foreign physiological institutions, by Dr. Tigerstedt. Referring to the development of physiology during recent years, the speaker described some of the principal institutions abroad, having visited forty of this kind. A similar one, on a smaller scale, was being established at the Carolina Institute in Stockholm.—The President, announcing the death of Dr. Regnell, the Brazilian Mæcenas, referred to the valuable botanical collections he had presented to the Upsala University.—Prof. Aurivillius exhibited a collection of butterflies, preserved by Herr E. Holmgren by removing the intestines and inflating the specimens. They were in splendid condition, the colours being particularly bright.—On the habits of the eider-duck and the dottrell, by Dr. Sundström. The speaker stated that careful study had proved that the eider-hen does not, as is so generally supposed, take her young during the summer into the ocean, but remains among the islands on the coast. The bird had greatly increased in the south of Sweden during the last few years.—On thunderbolts, by the same.—Herr Neves reported the receipt from Finland of eggs of the eagle, *Aquila clanga*, and the snipe, *Terekia cinerea*.

THURSDAY, NOVEMBER 20, 1884

BACTERIOLOGY

AMONG the most striking of the recent rapid advances of science is the development of what we may term bacteriology. For more than one hundred years a debate had been going on as to the origin of the minute forms of life which were present in decomposing organic materials, but till the publications of Cagniard-Latour and Schwann no part was assigned to them in the production of the chemical changes which these materials undergo. It was not, however, till the publication of Pasteur's papers on the alcoholic fermentation and on spontaneous generation little more than twenty years ago that any sound basis was obtained for the idea that a micro-organism was able to cause fermentation. The science of bacteriology really dates its commencement from the first publication of Pasteur's papers. Following rapidly on this work, researches have been carried on which have now demonstrated that all the fermentations belonging to the same class as the alcoholic fermentation are due to the development of micro-organisms, and that bacteria are most important factors in Nature, being the chief agents by which the complex organic constituents of plants and animals are brought back to simple forms capable of serving again as food for plants.

But the researches have not been confined to the study of fermentations. In 1851, Rayer and Daraine observed in the blood of animals suffering from splenic fever the presence of numerous small rods which were supposed to be crystals. On the publication of Pasteur's papers, Daraine again took up the subject, and came to the conclusion that these rods were bacteria and the cause of the disease. For some years little was done in this direction, though microscopical observations on the occurrence of bacteria in various diseases were described. With the publication of the investigations of Koch and Pasteur on anthrax, and more especially of Koch's modes of cultivation, a new start was made, and these researches have since been carried on with a certainty and a precision that could not have been anticipated, and have led to the accumulation of a large amount of knowledge with regard to the causation of infective diseases. A causal relation has been established between bacteria and splenic fever, various septicæmic affections, and infective diseases in the lower animals, tuberculosis, glanders, erysipelas, and other diseases in man; while in a number of other cases, in which the causal relation has not been completely demonstrated, facts have been made out which render it extremely probable. In spite, however, of this large addition to our knowledge, the subject is as yet little more than in its infancy, numerous questions of the greatest importance and likely to lead to the most important results still requiring investigation.

Apart from its purely scientific interest there is perhaps no department of science which so nearly concerns the health and well-being of the community, and already important practical results have been obtained, affecting medicine, industry, and public health. Following closely on Pasteur's early publications, and as a direct result of them, we have the great revolution in surgery brought about by Sir Joseph Lister, resulting in such improvements in the management of wounds as have been the means of saving numerous lives and of greatly enlarging the scope of surgical interference. Our knowledge of the value of disinfectants, of the mode of spread of infective disease, and of the precautions necessary to prevent its spread has also been very largely increased, and must lead to great improvements in hygiene. Nor must we omit to mention the valuable experiments begun by Toussaint and Pasteur, and now being carried on to a large extent by Pasteur, on the attenuation of virus and the conversion of virulent micro-organisms into useful vaccines. This has been demonstrated to be possible in the cases of chicken cholera, anthrax, pig typhoid, and possibly hydrophobia, and has been put practically into force in France in the case of the first three affections. Useful facts affecting various industries have also been made out. The deplorable condition of the silkworm industry some years ago and Pasteur's investigations thereon are well known, and have led to the restoration of the silk manufacture; while his work on diseases of beer and wine, and the work of others on various fermentations, have proved of the greatest benefit.

While some of this work has been done in this country, by far the greater part has been done abroad, more especially in Germany and France, where its importance is recognised, and where special facilities are afforded by the Governments and various public bodies. In Germany especially, besides the laboratory, supported by the Government, in which Dr. Koch works, a number of similar institutions are being established throughout the country; and in France the laboratories of Pasteur and others are established and supported by the Government and by various municipal authorities, every facility for carrying on these researches, and the necessary funds, being provided. In this country, on the other hand, there is no laboratory of the kind, and what work has been done has been by individual investigators working at their own expense, and often without suitable accommodation. To carry on this work a considerable amount of apparatus is necessary, an assistant is required, and the use of a laboratory where animals can be kept is essential. Without the help of a trained assistant, the investigator's time must be largely taken up in the sterilisation and preparation of his cultivating media and in other manual work, leaving but little time for actual investigation, more especially if, as is often the case, teaching or medical practice must be carried on as well in order to earn a livelihood. How different are the conditions where a well-equipped laboratory is provided, where trained assistants are present, and where a salary is given sufficient to enable the investigator to devote his whole time to the work. Surely it would be possible to establish a proper laboratory in this country.

That the matter is felt to be of importance was shown last summer by the fact that the Executive Council of the Health Exhibition devoted a considerable sum to the establishment of a model laboratory under the direction of Mr. Watson Cheyne, in which many of the results and the most recent methods of investigation were shown. This laboratory was visited by large numbers of scientific men and others, and the hope was universally expressed that the model would become the basis of a permanent institution. We

are glad to hear that the Executive Council of the Exhibition are taking into consideration the advisability of devoting their surplus funds to this object, and we hope that they may ultimately resolve to do so. They could not better advance the cause of hygiene, and more fittingly carry on and perpetuate the work begun by the Exhibition. The sum required to build and adequately endow such a laboratory would of course be considerable, but there can be little doubt that, once the matter is started, various public bodies will aid in the work, while a suitable site at South Kensington might be obtained from the Commissioners, as there the laboratory would be in the vicinity of those belonging to the Science and Art Department and the City and Guilds Institute.

HEROES OF SCIENCE

Heroes of Science: Mechanicians. By T. C. Lewis, M.A. (London: Published under the direction of the Society for Promoting Christian Knowledge, 1884.)

IN this volume short histories are given of the following inventors:—Watt, George Stephenson, Richard Arkwright, Crompton, Maudsley, Joseph Clement, James Nasmyth, Whitworth, and Babbage. The facts told of the lives of these men have been gathered from reliable sources and are accurate. It is unfortunate that Prof. Lewis did not introduce more of these facts in his book instead of using up its very limited space by inserting an inordinate amount of moralising, which is extremely tantalising, and makes it often difficult to proceed owing to the impatience which it causes. No words that could be used by way of reflection, even by a great writer, could add much to the moral stimulus afforded by the simple narrative of the lives of men like Watt and Stephenson, and the style which we encounter here, although often very ambitious, signally fails in attaining its mark and, instead of increasing our admiration for the men described, adds an unwelcome tinge of the ridiculous to the account. Thus in describing the early life of Arkwright we meet with these sentences amongst others:—"Before this he was probably as well off as most itinerant dealers in hair of his rank, but this first decisive step of his" [that from a village barber to a dealer in hair] "was enough to show that he could be dominated by an idea even to the length of relinquishing some certainties of advantage." "Whilst he was doing his unexciting work of preparing orderly cover for the outside of other men's heads" [this means making wigs] "he was—apparently too without much mental excitement—introducing order and exercising thought in the interior of his own; in consequence of which it appears that, whatever he did in those days to cover the heads of thinking and thoughtless men and women with a fair show of hair, he has done more for us in providing for the inside of ours some furniture of profitable thought," &c.

Amongst many curious pieces of information which we come across we may draw attention to the following piece of social history probably hitherto unknown. "When Adam delved and Eve span, or when their descendants first adopted this division of labour, the work of digging was carried on in the sweat of the brow, it required strength, and was relegated to the man; the process of spinning, which required less strength than dexterity, was assigned to the woman." Neither in Genesis nor in the *Transactions* of the Anthropological Society do we remember having seen any account of this early example of the division of labour. Valuable practice in English construction after the manner of the old so-called orthographical exercises, might be set on this book, by asking boys studying English to criticise and explain (if possible) the meaning of the phrases in italics in the following sentences:—(Page 155) "In him we look in vain for *the disinterestedness that endears self-sacrifice to us.*" (P. 253) "The revolution that was being effected by the introduction of machine tools, was, like all revolutions, sure to meet with resistance. It is not too much to say that by its means *a little one became a thousand.*" As a piece of grandiloquent writing, of which we here find many samples, we may instance this (p. 211):—"Modern inventions succeed one another like the links of a golden chain forged by men of god-like skill for our support, and indeed for our elevation. The cloak of an Elijah often falls upon the shoulders of an Elisha."

We are curious to know if the assailers of classical education have ever used stronger language than is here employed in describing Nasmyth's studies (p. 212):—"The classical education they had attempted with little success to give to him there was not at all suited to his bent. He asked for food, and they gave him a nauseous poison." In these days when the working man is so courted and admired, we should have thought it, to say the least, unnecessary to inform the readers of this book that (p. 202) "in all his (Clement's) work . . . there was an interest in his art which in his case raised it above the labour of a calling," or (p. 232), "in labour such as his (Nasmyth's) there was no degradation" This too after he had become an employer of labour himself!

Besides committing great errors of style, the author occasionally errs as to matters of fact. Thus (p. xiv.), he says, "The world has had to be content with using from two and a half to four pounds of coal for" one horse-power. The limit would have been put much lower had he studied the records of the engines of the best American liners. On p. 57 a description is given of "the double-acting steam-engine, in which steam is admitted to press the piston both upwards and downwards, the piston being also aided in its motion by a vacuum produced by condensation on the side towards which the steam is pressing it." To say that the piston motion is "*aided*" by the vacuum on the opposite side to that on which steam is acting is a curious way of representing the fact that without such a vacuum no motion of the piston would be *possible.* The definition of parallel motion given is new. On p. 58 we read, "The specification included . . . the contrivance for parallel motion or for making the piston-rod move perpendicularly up and down without chains or perpendicular guides, or untowardly friction, arch heads, or other pieces of clumsiness."

The book, which we are informed (p. vi.) is intended for boys, does not give enough explanation. The descriptions of inventions given are of the briefest, and will be quite unintelligible to any one who has not already spent a considerable amount of time in studying them elsewhere. If Prof. Lewis had been content to omit the wearisome reflections which he has placed in the book, and had,

instead, inserted a few engravings, he would have made the book more entertaining and less trying to readers of only average patience. If he had spent more time on the solid parts, and less on its affected adornments, he would have produced a valuable and interesting book.

OUR BOOK SHELF

The Student's Guide to Systematic Botany. By Robert Bentley, F.L.S., M.R.C.S. Engl., &c. (London: J. and A. Churchill, 1884.)

THIS little book, which aims chiefly at supplying the wants of medical and pharmaceutical students, represents fairly what was the state of systematic botany in England twenty years ago. The bulk of the book is occupied with a detailed description of the natural orders of Phanerogams, while the Cryptogams are dismissed in fourteen pages. But it is not only by the very cursory way in which these plants are treated that the student is led to underrate the importance of the morphological differences by which the various groups of Cryptogams are distinguished; the heterogeneous series of Algæ and Fungi are described as "orders" comparable, as regards the terms used in the classification, with the orders of the Angiosperms. Again, in the text, signs of antiquity are numerous: for instance, in distinguishing the Cryptogamia from the Phanerogamia (p. 14) we find that the former "are reproduced by spores, and are therefore acotyledonous," a sentence which implies that the spore is the homologue of the seed! In describing the ferns no mention is made of the prothallus, antheridia, or archegonia, though the latter are described as occurring in the mosses, and resulting in the formation of a "sporangium." These examples are sufficient to show that this book does not meet the present requirements even of medical students, who now have access to other text-books, treating of the principles of systematic botany in a manner more in accordance with the present state of the science than the "Student's Guide" of Prof. Bentley.

The Electrician's Pocket-Book. The English Edition of Hospitalier's "Formulaire Pratique de l'Électricien." Translated, with additions, by Gordon Wigan, M.A., Barrister-at-Law. (London, Paris, and New York: Cassell and Co., Limited, 1884.)

M. HOSPITALIER'S "Formulaire Pratique de l'Électricien," of which the work before us is a translation, has become well known in this country as a useful compendium of data and rules for electrical work, and Mr. Wigan has done good service in putting an English version within the reach of the numerous class of practical men whose knowledge of French is, to say the least, limited. He has executed his task very creditably, as the book, so far as we can tell without a minute examination of the numerical and other data, seems fairly accurate and trustworthy. The least satisfactory part of this work, as of all others of the same kind which we have seen, is, we think, the synopsis of theory which is given along with the data and other practical information. In these days of excellent elementary and advanced text-books of theoretical and to some extent also of applied electricity, the necessarily detached and somewhat scrappy statements of theory which partly fill the "pocket-books," are little called for, and the space occupied by them could be used to better advantage for other matter, or the book lightened by their omission.

In looking over the book we have found some slight faults in descriptions of instruments, &c., which might be mended in a new edition. For instance, in p. 75, the author (? translator) has entirely misapprehended the use of the V-groove in Sir W. Thomson's "hole, slot, and plane" arrangement for insuring that an electrometer or other instrument is replaced, after being moved, in exactly the same position. The "hole" is not simply a hole, but a conical hollow, and the primary object of having a V-groove is to obviate the infinitely perfect fitting which a second hollow would render necessary. Again, the description of the quadrant electrometer (p. 107) does not seem likely to convey any clear idea of the construction of the instrument.

The subject of the testing and laying of submarine and land telegraphs is not very fully treated, and the data in this department is also comparatively meagre. On the other hand, descriptions of a large number of dynamo-machines and statements of experimental results regarding their behaviour in electric lighting and transmission of power form a marked feature of the book, and we need not say that even roughly approximate information of this kind in a collected form is very valuable.

On the whole, we feel sure that the work will form a valuable pocket companion to the electrical engineer.

A. GRAY

Science Note-Book. By C. H. Hinton. (London: John Haddon and Co., 1884.)

THE constitutive elements of Euclidean geometry are the straight line and the circle—two continuous curves, which stand to one another in a certain relation of reciprocity, and the actual production of which, as Newton has already remarked, demands certain mechanical appliances—the ruler and the compass. If we add to the above that Euclid's method is the synthetical, then his system of geometry is defined without ambiguity. The principal lack of this geometry, which was not clearly brought to light until the second half of this century, consists in this, that it is limited to considerations of quantity, and only treats secondarily of the relations of position.

Poncelet has recognised this defect, and has laid the foundations of the so-called modern geometry, which, during the last few decades has so greatly enriched the science of space as well in positive results as in new methods.

Euclid's system, however, has not been uprooted, but only completed on a side on which it was wanting. In schools the "Elements" of the Alexandrian geometer are generally taught, while descriptive geometry and the theory of higher curves (as taught in the University course) are chiefly based on modern methods.

In a handy introductory publication Mr. C. H. Hinton, Science Master at Uppingham School, has brought forward points of view which form a third method of geometrical investigation, fundamentally different from both those mentioned above. It is not opposed to either, but appears as a welcome complement of both. The author does not presuppose continuous elements as has been generally done, but only sets of points equally distributed in two dimensions, which, merely for the sake of convenience, are connected by straight lines. As in Euclid's geometry an infinite pencil of rays can be drawn from every point, so the conic sections may be determined by a method of counting discrete points. The problem of division of a given line into parts, and of the construction of parallels can be generally solved.

The practical advantages of this new method in the form in which it is now published are purely educational, though it is wholly based on the principles just mentioned. The author has succeeded in bringing new ideas into simple and attractive form, which enables the youthful and inexperienced mind in a very short time to acquire a mathematical knowledge of space which is of much value in facilitating a subsequent thorough understanding of Euclid and of modern geometry. The work has an encouraging appearance, inasmuch as it does not contain any hypercritical transformation of the system of our old Euclid (in which respect so many authors have recently

erred), but makes us acquainted with new thoughts which in themselves are worthy of pursuit, and which in their present form are of general educational service.

KARL HEUN

The Dynamo: How Made and How Used. A Book for Amateurs. By S. R. Bottone. (London: W. Swan Sonnenschein and Co., 1884.)

THIS little book of 75 pages is designed to give to amateurs practical information as to the construction of a small working dynamo-machine. What is aimed at is the building up of a machine capable of being worked by hand and suitable for experimental purposes. The dynamo-electric machine is one which an amateur mechanician may very well undertake with every prospect of success and satisfaction; and the book before us is thoroughly practical and is pleasantly written, and will, we feel sure, be acceptable to many. We are acquainted with books on the steam-engine for amateur constructors; but a dynamo of simple form is easier to make than a steam-engine, and will, we think, when made, prove a far more useful and pleasure-giving toy than a steam-engine such as an amateur can put together. When all is done, a steam-engine of amateur construction can do little more than go round and round; but a host of experiments in electric lighting and in electro-chemistry may be made to follow on the successful completion of a small hand-dynamo.

The author describes the making of a very simple dynamo with a kind of shuttle-wound armature. All his instructions are clear and, as we have already said, thoroughly practical. The only question on which we have any doubt whatever is whether, at any moderate speed of turning, the dynamo will yield so much current as the reader is told he may expect.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Natural Science in Schools

As one who has been engaged in teaching science in schools for the last ten years, I should like to make some remarks on Prof. H. E. Armstrong's interesting lecture, published in NATURE of November 6 (p. 19).

(1) In the first place I would like to express my agreement with his weighty opening words. The main body of schoolmasters are so completely without any science-training that it is very difficult for many of them to see its necessity or even its advantage. The younger generation of masters in the large public schools, moreover, having come to the work in recent years have not, like their predecessors at Rugby, Clifton, Taunton, and elsewhere, had an opportunity of observing the gain of life and general intelligence which followed the introduction of science into the regular school work, in those schools where it was taken in hand seriously and with enthusiasm. Others, again, have more or less forgotten. Consequently it is still necessary to point out that, excellent as is the training given by the mathematical and classical teaching of our schools, yet that by itself it is not enough. No excellence in the *method* of teaching classics and mathematics will compensate for this, to adopt Dr. Armstrong's words, that they fail to develop "the faculty of observing, and reasoning from observation and experiment," that they fail to give any idea in the concrete of the nature of evidence. No doubt many able men educated on a classical or mathematical basis, can observe and reason from observation; this is, however, in spite of, and not in consequence of, their training. To the majority the deficiency is a serious matter, and probably it goes far to account for the peculiar opinions of scholars one sometimes hears expressed by practically successful men, and produces the unfortunately too prevalent idea among them that, if their sons are to go into business and to succeed, they must not stay at school too long—they must not learn too much book-learning. It should, then, in addition to its other services, be the function of science in education to keep awake and develop the natural practical intelligence of our lads, and so to make up for the deficiencies in this respect which accompany the otherwise vast advantages of a literary and mathematical culture.

(2) I suppose that no science-teacher will fail to agree with Prof. Armstrong that we have by no means exhausted the possibilities even of our present opportunities. As my object is to advocate advances, however, I will not dwell upon that part of his remarks except to say that I am sure a closer acquaintance with the methods of a good many of our science schoolmasters—with the time at their disposal, the laboratories they work in, and their boys, in short with the conditions under which they work—would satisfy him of the considerable value educationally, when it is properly done, of much that he condemns, and also that something of what he advises is already being attempted.

The lectures in schools are already, I should say, usually more or less of the nature of the tutorial classes which he recommends, and, whilst we recognise a great educational value in analytical work, if properly taught, we shall, I feel sure, be ready to abandon that for something better as soon as it is ready for us.

Having said this much, I hasten to add that I quite recognise, on the other hand, the value of Prof. Armstrong's suggestions, and that I am at present conducting a class on a system which in principle is very like that which he suggests. Indeed it is in several important points the result of suggestions made to me by Prof. Armstrong some two years since. More particularly I am trying a form of what I may call the problem method of practical teaching, which Prof. Armstrong so strongly recommends.

As it is only lately that we have had the necessary accommodation for this attempt, my experience is not very great. But I have learnt a good deal, and, as Dr. Armstrong's lecture brings the question into prominence just now, I may say what my experience is so far. Remembering that economy of time is of the first importance, and that our object in teaching science in schools is to promote a certain attitude of mind towards Nature rather than to produce skilful manipulators, I am not yet certain whether courses of work in which each pupil, with assistance, suggests and carries out the experiments himself, or tutorial classes, in which the suggestions are as far as possible elicited by the teacher from the class, and then the work is carried out by the teacher before the class, will give the best results. I tried the latter plan some years ago with beginners at Taunton with the most encouraging results. I believe, however, that a combination of the two methods will finally prove best. There is no doubt that greater interest is created when the pupils do the work themselves; on the other hand, much time is lost, at first, through difficulties of manipulation. Accordingly I am trying to arrange things so that the simpler experiments shall come together and be done by the boys; and when anything more difficult has to be done we fall back upon the tutorial method. I have no doubt of the advantage of practical work combined with some form of lecturing, *if there is time enough.* But in schools there rarely is time enough given for both. As an introduction to a course of lessons on the present system a practical course or a tutorial class on the lines proposed by Dr. Armstrong will certainly be of great value, and one or the other must, I think, be possible in almost every school.

(3) I will now pass to some points not discussed by Dr. Armstrong in which it appears to me that chemical teaching at present is open to improvement. I always aim, myself, not at informing my classes of chemical facts or principles, but, as far as possible, at leading them to discover them for themselves. In this I am more or less hampered by the absence of sufficient appreciation of the bearing of the simpler physical facts of Nature upon chemical processes. This I supply as far as I can. But I believe, and I am trying the experiment, that a real advance in the value of chemistry as an education will be made if, as an introduction, the beginners are put through a course of practical problem work which brings out in every possible way the dependence of chemical operations upon the simpler physical properties of matter; such as volatility, solubility, &c.

(4) I was told the other day, by a great authority on educational matters, that science has had a distinct and good effect on grammar-teaching. I think, on the other hand, that science-teachers have been rather slow to recognise and imitate one

particular excellence in the method of language-teachers. I refer to the practice of making the students acquainted with the works of great writers at the earliest possible period. I should like to see fairly advanced classes of chemical and other students, in schools and elsewhere, reading, with assistance, some of the more suitable memoirs of such men as Davy, Graham, and Faraday. I do not advocate the complete abandonment of text-books, but I should rejoice greatly if their use could be considerably restricted and something better substituted. Has not this neglect of the original writings of great workers by our teachers something to do with the subsequent neglect of research by so many of their pupils? There is of course this practical difficulty in the way of what I propose—that original memoirs are not at present obtainable in a form in which they can be put in the hands of whole classes of students. If my suggestion should prove acceptable to even a few teachers however, that is a difficulty which could be very easily surmounted.

(5) When any one proposes to himself a change in his mode of teaching, unless his position is quite exceptional, he always finds himself confronted by one solid difficulty, viz. public examinations of one kind or another. Teachers at first inspired the examiners. Now they find themselves too often helpless before them. In the face of our various examining Boards individuals are nearly powerless. The time seems to have come when an association of science-teachers for the improvement of science-teaching is a real necessity—something more or less resembling the Association for the Improvement of Geometrical Teaching. Such a body would often be invaluable. It could, by the appointment of committees, and perhaps by pecuniary help, promote such experiments as I have suggested in Paragraph (4). In cases such as the recent unfortunate action of the War Office, it might be expected to do good work by replacing individual by organised action. And it could hardly fail, by bringing teachers and examiners into contact, to do much to make advances in teaching more possible than at present.

My various remarks on so many points have necessarily been brief and incomplete. I could not, in the form of a letter, go *fully* into questions of advantage, disadvantage, and difficulty. I shall have amply attained the object I have had in view if I have helped to draw attention to these important matters.

W. A. SHENSTONE

Do Flying-Fish Fly or Not?

I HAVE crossed the Atlantic and Indian Oceans many times and at different seasons of the year, but until my last voyage to Calcutta I was unable to answer this question positively. For days together, aided at times by a powerful field-glass, I have endeavoured to establish satisfactorily whether these nimble little fish used their membranous wings after rising above the surface of the sea or not. An old and valued friend, the late Charles Kingsley, on his voyage to the West Indies, so graphically painted in the pages of "At Last," records his opinion in favour of the wings being employed as a means of propulsion through the air after the fish quit their more natural element, and I certainly inclined to the same belief, although, owing to the "ever-vexed" condition of the Atlantic, I found accurate observation impossible. In the Indian seas the fish appear at rarer intervals, and limit correspondingly the chances of watching their movements.

On a blazing afternoon in May last, on board the steamer *India*, some hundred miles off the African coast on the way to Ceylon, I had the first and only opportunity I ever enjoyed of establishing beyond dispute this vexed question, which I am not aware has hitherto been settled. The sea was perfectly calm, covered here and there with a yellow scum which exhaled a fresh unpleasant smell like a beach covered with sea-weed at low water. From the spar-deck above the cabins, which were fitted up in the fore-part of the ship, I could descry at frequent intervals shoals of flying-fish rising and apparently fluttering from 50 to 100 yards before dipping again into the mirror-like surface of the ocean. Along with several of the passengers—some of them provided with field-glasses—I vainly endeavoured to make certain whether the fish did or did not make use of their wings after leaving the water. Opinions were divided, for, owing to the rapid motion of the fish, it was impossible to keep any one of them long enough in the field of vision. It occurred to some of us at length to look over the bows of the steamer, and there we saw a sight not soon to be forgotten. The flying-fish appeared frequently shooting upwards in large numbers from the blue glassy depths directly beneath us, as the shoals were disturbed by the vessel's cutwater, and their every movement plainly discernible while under water and from the moment they rose "winnowing the waving element" with expanded wings and tail, bent on escaping the pursuing craft, until they dipped again into the sea for shelter or to obtain fresh impetus for continued flight. I satisfied myself, and so did my fellow-watchers, that after a certain number of strokes with wings and tail—from twenty to thirty, varying with the dimensions of the fish—which we repeatedly counted, as they left corresponding impressions on the oily surface of the water, these appendages were not employed to accelerate, but merely to sustain, the flight while the fish remained in the air. The curved impressions left by the wings on the water appeared, as nearly as I could judge, from twelve to eighteen inches apart on either side of the fishes' course until clear of the water. The tail left no perceptible imprint, but could be clearly seen waving from side to side, adding doubtless considerably to the impulse. After rising out of the water the wings and tail remained ridged, but in some instances were slightly twisted to preserve the equilibrium. Occasionally a fish appeared to lose its balance in the hurry of escape, and toppled over in a ridiculous fashion.

The yellow scum also attracted attention, tinging the ripple at the bows a deep orange. I had some of it brought on board, and a fellow-passenger of an entomological turn placed some under a powerful microscope, but failed to determine the species to which it belonged. Ten years ago, near the same place, I observed the water assume a dirty yellow tinge, as though it had suddenly shoaled, while the same unpleasant smell was perceptible. The discoloration and smell I found to be due to the presence of vast quantities of animalcula, about a quarter of an inch long, semi-transparent, jointed like a cane, and about the thickness of a small needle.

ROBERT W. S. MITCHELL

8, Garden Reach, Calcutta

Earthquake Measurements

I REGRET that Prof. Ewing should take so much to heart my criticisms of his results of earthquake registration. I think that if we can get a single movement instead of a double one we gain much by halving the errors of double registration, extra friction, complexity of calculation, &c., all causes that tend to increase the imperfection of the results.

Neither did I intend to disparage seismological investigations on the plain of Yedo, but it does seem to me that the first thorough study, such as Prof. Ewing and others have initiated, should be in a locality where the minimum of disturbing influences would be able to complicate the results. In fact, we should expect much more progress in arithmetic in a child which commences by learning to count than in another that is immediately put to study fractions. I should never suggest that one earth-shaken locality should be continuously studied more than another when once we have decided upon the most serviceable and accurate registering apparatus.

Now as a resident in a country continuously shaken by earthquakes, many of which are disastrous, and where investigators are few and far between, we want instruments that give the least complicated tracings possible if we are to find observers amongst inhabitants of the Italian provincial towns. The same thing holds good to a variable extent in other countries.

Again, hardly any one would accuse me of claiming entire originality for the principle in the apparatus described. For example, every one knows that the pendulum has been used as a seismograph for centuries even. All that I claim is a combination of different forms of actuating and registering apparatus, with a few novel introductions, for it is practically impossible to *invent*, in the true sense of the word, a new seismograph any more than a new locomotive.

Perhaps, in my critic's opinion, we have reached perfection in seismographic instruments, which it appears is not shared by many workers, as the continual new suggestions and modifications indicate, as does also the fact that throughout all the observing-stations so far instituted it is rare to find two provided with similar instruments.

In regard to Prof. Ewing's last paragraph, perhaps experience will determine whether my suggestions do really lie outside the sphere of practical seismology.

In conclusion I shall be happy to hear suggestions for any improvements from others, for in my own humble opinion we do not yet possess a single seismograph that reaches near to perfec-

tion (my own of course included), so that we may still consider the instrumental investigation of earthquakes far from a settled matter, and one to be more fully worked out.

Naples, November 10 H. J. JOHNSTON-LAVIS

Autumn Flowering

REFERRING to your article on autumn flowering (p. 13), I may mention that my garden primroses are now flowering again, and a laburnum is in flower in the garden of one of the houses on this road. I was in Paris in September 1861, and saw many horse-chestnuts in flower. The summer of 1861 was unusually warm and dry on the Continent, though I believe not in the British Islands. JOSEPH JOHN MURPHY

2, Osborne Park, Belfast, November 14

The Northernmost Extremity of Europe

"A NORWEGIAN" (NATURE, p. 17) says that my description of Knivskjærodden as a low glaciated tongue of rock is hardly correct. As Norwegians ought to, and generally do, know more about their own land than do foreigners, I will quote Tönsberg, whose "Norge" is admitted as a high authority by all. Describing the scene displayed from the edge of the precipice of the North Cape, he says: "Beneath you at a distance of one-eighth of a mile, you see the *long low* Knivskjælodde, *which is undeniably the most northern part of Norway.*" The picture in his book (from a photograph) shows the northward extremity of this projection as washed over by the waves and its *western side* precipitous, as I saw it.

I sailed round it twice, more than ten years ago, halting in front of the North Cape for half an hour, and can only smile at the attempt to claim the northward supremacy of Knivskjærodden as a new discovery or one demanding further verification. In my copy of Munch's map (1852) it is shown as projecting a little further north than the North Cape.

Tönsberg further confirms my statement concerning the elevation of the neighbouring Arctic headlands, which "A Norwegian" also contradicts. Sverholtklubben, according to Tönsberg, is twenty-four Norsk feet higher than the North Cape. I should have added that the measurement I gave was in Norsk feet. Measured in English feet, the height of the North Cape is 1004 feet; that of Sverholtklubben 1029 feet at the edge of the cliff. There are about a dozen other headlands of similar magnitude between North Cape and the Varangerfjord.

W. MATTIEU WILLIAMS

Breeding of the Quadrumana

HAVE any of your readers any experience of the production in captivity, of a *second* generation of any of the quadrumana? At least twelve out of about eighty species kept in the Zoological Gardens have bred during the past thirty years—the lemurs forming a large proportion—and the Rhesus more frequently than any other monkey. I presume that even a *first* generation of any of the anthropoids is unknown—except possibly of the gibbon (?). The disposition and moral character (in the widest sense) of no species of monkey whatever approaches that of the dog. May not this be due to the absence of inheritance (to which the dog owes so much) of the gradually accumulated cultivation of these qualities through association with man? The dog has enjoyed all these advantages. The monkey cannot, owing to the impossibility of rearing a succession of generations in captivity. Does the experience of your readers, who may have studied a first generation of monkeys, point to any improvement on the parent stock in dis osition and character? So far as I have been able to judge from individuals in public collections, the mere mental power of these animals conspicuously exceeds that of any others. I should be glad to know whether this opinion is shared by those who have had more extended opportunities of observation. ARTHUR NICOLS

Fly-Maggots Feeding on Caterpillars

YOUR correspondent, Dr. E. Bonavia (p. 29), is mistaken in supposing the flies bred from his butterfly-chrysalis were "house-flies." They belong to the sub-family *Tachininæ*, which is of very large extent, comprising several hundreds of species in Europe alone, and all probably parasitic in other insects. The "house-fly" belongs to the sub-family *Muscinæ*. The mistake is very pardonable, for there is often great external similarity in form, colour, and size, and it is one frequently made in this country. R. MCLACHLAN

Clarendon Road, Lewisham, S.E., November 14

IT might interest Dr. E. Bonavia (November 13, p. 29) to know that it is not an unusual circumstance to find the larvæ of the house-fly in the nests of *Vespa vulgaris* and *V. germanica* feeding upon the live bodies of the larvæ and pupæ of the wasps. Occasionally I have found nests in the summer-time quite deserted by the wasps, all the pupæ in the cells having been eaten by the maggots of house-flies and other *Diptera*. F. W. ELLIOTT

Buckhurst Hill, Essex, November 18

The Sunday Question

THE announcement that, "after opening the Free Library on Sundays for two months, the Town Council have resolved to close it again *in consequence of the small number of visitors*," seems to indicate that the Town Council of Chester were as wise in deciding to close the Library as they had previously been in giving the people of Chester an opportunity of spending a portion of their day of rest in the Public Library, where those who do not possess libraries of their own can obtain access to the wisdom of the ages as stored in books.

If the facts are as stated, no one can complain of the action of the Chester Town Council, though some would have been glad to have seen a little more patience with people who for so long have been compelled to spend their Sundays when not at home either in the church, the public-house, or the streets, all of which may be attended with advantage and profit by free and intelligent men and women; but when men are driven to either of these places, what should be a blessing becomes in too many cases a curse.

However, as I have said, we have no right to complain of the Town Council of Chester closing the Public Library on Sunday if there is no considerable number of the people of the town desirous of using the institution on that day. In civilised communities representative authorities such as town councils and parliaments are only justified in spending public money on institutions when at least a considerable section of the community desires it.

The Sunday Society bases its claim for the Sunday opening of the British Museum, the South Kensington Museum, the Natural History Museum, the National Gallery, and the Bethnal Green Museum on the ascertained fact that very large sections of the community do desire to visit them on Sundays, and if it be replied that there are more people who have no such desire and therefore these institutions should be closed, I answer that that argument would close the whole of them on every day in the week, for no one will for a moment contend that a majority of the people of the United Kingdom have visited, or can possibly visit, these national exhibitions of the wonders of the universe and what we call its highest product—man.

But the benefit of these institutions is not confined to those who actually visit them. The sermon of the Puritan divine and the lecture at the mechanic's institute are alike indebted to the British Museum and the other institutions named.

Let the trustees of the British Museum follow the example of the Town Council of Chester and open the Museum on Sundays for two months, and the question, so far as the Sunday Society is concerned, will be settled for ever. I will venture to say that after such an experiment the British Museum would never again be closed on Sundays, and with such an example in the centre of the metropolis, no Sunday Society would be longer needed to advocate the opening of museums, art galleries, libraries, and gardens on Sundays.

The statement that at Keswick the "Sunday-opening experiment had been tried and abandoned" is true, but it should be explained that the Library at Keswick is not a public institution in the sense of being supported by rates and taxes, and is under the sole control of the vicar of the parish. It was the late vicar who closed the Library on Sundays, and I have the pleasure of announcing the fact that the Sunday-closing experiment has been tried and abandoned. The present vicar, the Rev. J. N. Hoare, did not decide to do this on his own authority, but he convened a special meeting of the Committee to consider the question,

when it was decided to again open the Library, during the winter season, on Sundays. MARK H. JUDGE,

Honorary Secretary of the Sunday Society

A Pugnacious Frog

A SHORT time back, about 6 o'clock in the evening, just as it was getting dark, hearing a squeaking noise below my veranda, I got up to look, and saw a most amusing sight, viz. a fight between a frog and a bat. The latter was evidently getting the worst of it, but at last suceeeded in getting away for a time from its opponent; the frog again attacked it, but this time *he* was glad to cry "quits," as the bat turned on him and beat him off, afterwards managing to hide somewhere so that we could not find it; the frog, however, was sorely bitten about the nose, and was in a sad plight. I do not know how the bat could have been on the ground, but it had probably fallen from its nest during the day, and was waiting for the evening, when the frog espied and attacked it with the bef re-mentioned result.

EDWIN H. EVANS

Margapala, Soemedang, Java, October 13

A DISEASE-GERM MYTH

WE are indebted to a correspondent for the following curious note from Fiji:—

You may have seen Wilfred Powell's "Wanderings in a Wild Country; or, Three Years among the Cannibals of New Britain." If you have not seen it, pray send for it, for, though falling far short of what it ought to be, it is not without interest. At p. 167 he tells a story of native magic which reminds me of something I have read before.

A native doctor being called in to a patient "looking wretchedly ill," performs a little "devil-devil" business, and then blows some burnt lime from the hollow of his hand against the patient's stomach; "then he began to scratch the man's navel with one finger," gradually approaching his mouth to the fellow's stomach, and drawing in his breath. Presently he places his mouth close to the man's navel, draws back suddenly, retches violently, and——throws up a worm. This the worthy doctor does twice.

Powell says, "I looked at the worms, they were *unlike anything I had seen before*, and appeared as if they certainly might have come from a man's body."

Now see Bates on the Amazons, cap. ix.:—"This (the illness) the Pagá pretends to extract, he blows on the seat of pain the smoke from a large cigar, . . and then sucks the place, drawing from his mouth, when he has finished, what he pretends to be a worm. . . . Senhor John contrived to get possession of the supposed worm after the trick was performed in our presence, and it turned out to be a *long white air root* of some plant"!!

Wilfred Powell should have got that worm or another specimen, even if he had been compelled, in the interests of science, to explore the patient's stomach with a pickaxe.

When Macdonald, of the old surveying-ship *Herald*, was in these waters, he was daily searching for a specimen of the pearly Nautilus (*N. pompilius*), which is pretty common here. One day upon the reef at Nasamusovu he met a Fijian coming out of his canoe in which he had been fishing. He showed him the picture of a Nautilus, which the man recognised at once, and, in reply to a question put through an interpreter, said he had just eaten one. Macdonald got into a great rage at the loss of such a treasure, but suddenly checking his excitement and glancing rapidly over the native, he said to the interpreter, "Quick, ask him how long it is since he ate it."

But there was something in the eye and the tone of the doctor's voice that so startled the gentle child of Nature that, before the interpreter could open his mouth, he had taken to his heels and put half a mile of reef between himself and the man of science.

What awful thought passed through Macdonald's mind has not been left on record.

THE BUDDHIST THEORY OF EVOLUTION

THE theory of evolution held by adepts in Buddhism is the outcome of the researches of an immense succession of investigators, believed to be qualified for their task by the possession of spiritual faculties and perceptions of a higher order than those belonging to ordinary humanity. In the course of ages the block of knowledge thus accumulated concerning the origin of the world and of man and the ultimate destinies of our race, checked and examined at every point, verified in all directions, and constantly under examination throughout, has come to be looked on as the absolute truth concerning the evolution, past and to come, of man and the planets he is destined to inhabit. The initiated members or "adepts" of the Buddhist cult claim to have attained, through intense self-absorption, a knowledge of physical laws of Nature not yet understood by Western science, investing them with extraordinary powers known as spiritualistic, such as clairvoyance and the disintegration and reconstruction of matter by a simple effort of will. They claim in fact to be in possession of potential faculties which will only be generally developed in future stages of evolution. This religion, which is wholly unaggressive and seeks no converts, attracts many on account of its claims to be in accord with all established scientific fact, and by its incorporation of so patent a truth as the doctrine of evolution as an integral part of its system.

A brief examination of these claims, and a glance at the past and future of man's evolution as thus elaborated, can hardly fail to be of interest, if it fails to carry conviction.

It is impossible, and unnecessary, to attempt to follow briefly the mystic subtleties of belief that have fascinated the Oriental mind, and been to it for ages what the pursuit of practical science has been to Western nations. Shortly stated, the Buddhist divides the human entity into seven principles, the higher of which have not yet reached their full development. The first three are of the earth, and done with at death. These are (1) the body; (2) vitality, or the life principle, an indestructible force which attaches itself to other objects after the decomposition of the body; (3) the astral body, "an ethereal duplicate of the physical body," which can under certain circumstances become disembodied and visible as a ghost; (4) the animal soul, or seat of all animal desires; (5) the human soul. The other two can be passed over, as they are still in embryo, and belong to a wholly superior and future condition of existence. The fifth and, later on, the sixth principles make up a man's continuous individuality through successive incarnations.

The solar system consists of seven planetary chains. The one with which man is concerned consists of seven planets, through each of which he has to pass seven times in order to accomplish his evolution. These are the Earth, Mars, which is in a state of entire obscuration or rest as regards the human life-wave, Mercury, just beginning to prepare for its next human period, and four other planets which are composed of an order of matter too ethereal for telescopes to take cognisance of. The system of worlds is compared to a system of towers standing on a plain, each of many stories, man's progress being a spiral round and round the series, passing through each tower as it again comes round to it, at a higher spiritual level than before. The impulse to the new evolution of higher forms is given by rushes, not a continual flow, of spiritual monads coming round the cycle in a state fit for the inhabitation of new forms, and those which for milleniums have gone on merel

repeating themselves then start afresh into growth, and rise rapidly, through intermediate, to the higher forms. The spiral character of the progress, and the fact that the tide of life passes from planet to planet in gushes, accounts for the gaps in the various kingdoms of Nature. Each time a spiritual monad arrives on a planet it has a complicated process of evolution to perform. It is many times incarnated before it passes onward, and man has many incarnations in each great race, the normal sum being not far short of 800, with an interval of at least 1500 years between each, spent in the "world of effects, or heaven of ordinary theology." In the first planetary round man inhabited an immense but loosely organised body, and could not be called intellectual. In the second he becomes of firmer body, whilst in the third he is rather in form of a giant ape than true man, yet of concrete body and advanced intelligence. In the fourth, the present round, his intellect becomes fully developed, and he achieves enormous progress. We now approach the transcendental mystery of mysteries, our future development. The fifth round will be occupied with a struggle between physical intellect and spirituality. In the sixth round a state of perfection of body and soul will be attained which can hardly even be imagined; while as to the seventh round the occult teachers themselves are solemnly silent, it being altogether too God-like for realisation. At the end of each planetary round an intercyclic period of extraordinary exaltation must be undergone. It is by processes of occult training that adepts project themselves precociously into the fifth round, or possess themselves of the attributes of fifth-round men, so as to be able to explore the mysteries of Nature and of other states of existence, and to assimilate knowledge by clairvoyance independently of observation.

We now exist in the fifth race of the fourth round. The first and second races developed no civilisation, but the third and fourth did do so several millions of years ago, though no traces of such now exist. The periods of the great root races are divided by vast convulsions or geological changes, which cut them off at the appointed time, leaving only a few survivors behind, who rapidly relapse into barbarism. The fourth race lived on "Atlantis," and reached its apogee in "the Eocene Age," when this great continent showed the first symptoms of sinking, a process that occupied it down to 11,446 years ago, when its last island, Poseidonis, went down with a crash. "Lemuria" was drowned with its high civilisation and gods about 700,000 years earlier than Atlantis, or just before the early part of the Eocene Age, the relics of its third-race inhabitants existing in some of the flat-headed aborigines of Australia. The true Chinaman is interesting as a relic of the fourth race. The civilisations of the ante-Glacial period were superior to those of Greece and Rome, or the Egyptian, which was in its decadence 12,000 years ago. The uninhabited Arctic regions will prove not only to have enjoyed a tropical climate, but were likewise the seat of one of the most ancient civilisations of the fourth race. Atlantis belonged to the Miocene times, and the cataclysm which destroyed it came at the appointed time, "otherwise it would be impossible for the best seer to calculate the exact hour and year when such cataclysms great and small have to occur." The relics of these former civilisations are hidden in strata which have never been geologically explored, deep in the unfathomed ocean beds.

An important part of the Buddhist creed is the belief in the alternation of periods of repose with periods of activity. As man sleeps every twenty-four hours, and vegetation subsides and revives with the seasons, so rest periods follow each incarnation. The tide-wave of humanity flows on to each of the seven planets seven times, and passes through its seven races and ebbs away again, but the great rest period of our planetary chain does not begin until the seventh round of humanity is perfected. At an incalculably remote period the whole of the seven planetary chains of our solar system will pass into a period of rest, and finally the whole universe itself will have its great cosmic night. After the long night of a planetary chain the animal and vegetable world resume their arrested activity, but when the time arrives for all the planetary chains of our system to pass into their night, each planet, as the seventh-round man quits it, is annihilated instead of merely becoming invisible, and there is an outflow from every kingdom of its entities. These will rest in lethargic sleep in space until brought into life again at the next solar period, and will then form the soul of the future globe. We have every indication that at this very moment such a solar night is taking place, while there are two minor ones ending somewhere. At the beginning of the next solar day period the hitherto subjective elements of the material worlds, now scattered in cosmic dust, will form into primordial ripples of life, and, separating into differentiating centres of activity, combine in a graduated scale of seven stages of evolution. Every orb will pass through seven stages of density, until its solidification and desiccation at last reach a point when it becomes a relaxed conglomerate, and its constituent masses cease to obey the laws of cohesion which hold them together.

Evolution takes its rise in the atomic polarity which motion engenders. In cosmogony the active and passive forces correspond to the male and female principles. The attribute of the universal spiritual principle is to expand and shed, of the material principle to gather and fecundate. These become consciousness and life when brought together. Our planet, like an iceberg, is merely a state of being for a given time, and its present appearance, geological and anthropological, is but transitory and will pass away.

Such are the beliefs and doctrines concerning evolution [1] held by the Oriental scholar, who holds in pity the benighted ignorance of Western so-called science. The book from which they are gathered is sober earnest, and I am asked whether the Buddhist ideas on evolution are in accord with the discoveries of science. The mere statement of the belief, shorn of its mysticism, is a sufficient answer. The importance attached to the numeral 7 seems puerile, and its reason is not easy to discover; it is claimed that the colours of the spectrum and the notes of the musical scale are seven, and that there are seven kingdoms in Nature. There is one seeming scientific fact, however, which, though it has escaped the "adepts," favours so far the belief in evolution by gushes, and is still unexplained. The first appearance of many forms of life on our planet, it is well known, is very sudden. All the groups of Mollusca, and especially in the case of Ammonites, appear at once fully developed and in great variety of species, and never develop into anything higher. So with the Echinodermata, the Crustacea, Insecta, the different orders of fishes, many orders of reptiles, marsupials, ferns, and dicotyledons. All these seem to have been evolutionised in a very sudden manner, and as yet afford no grounds for controverting the Buddhist belief that they are well developed arrivals from other planets.

J. STARKIE GARDNER

THE RAINFALL OF 1884

THE water famine with which the towns of Manchester and Bradford have recently been threatened has served to draw public attention to the fact that the rainfall of the present year has been strikingly deficient. As the extent of the deficiency is, however, little, or at the best imperfectly realised, a few reliable statistics on the subject may be of more than ordinary interest.

The following table shows, for seventeen places situated

[1] Condensed from Mr. A. P. Sinnett's book, "Esoteric Buddhism" (Trübner and Co.), and as far as possible in his own words.

in various parts of the United Kingdom, the excess or deficit of rain which has occurred during the first, second, and third quarters of the present year, and also similar values for the month of October. In the last column we have the number of months in which the rainfall has been less than the average. It must, however, be explained that these numbers do not necessarily signify consecutive months. The values in the table have been compiled from the Monthly and Weekly Weather Reports issued by the Meteorological Office, and the averages employed have been those for the fifteen years 1866 to 1880.

Recording stations	Excess or deficit					No. of months with deficiency of rain
	January to March	April to June	July to September	October	The whole ten months	
England and Wales	per cent.	per cent.	per cent.	per cent.	per cent.	
York	+33	−54	−18	−70	−22	6
Stonyhurst	+31	−46	−21	−29	−13	7
Blackpool	+41	−32	−14	−45	− 2	6
Manchester (Prestwich)	+18	−44	− 8	−43	−14	8
Llandudno	+30	−32	−23	−66	−17	6
Leicester	−13	−27	−33	−39	−27	8
Hereford	+ 4	−19	−29	−70	−23	6
Cirencester	−11	−22	−29	−68	−26	6
Marlborough	+ 7	− 9	−37	−69	−21	6
Oxford	−20	−24	−41	−69	−34	10
London	−28	−37	−39	−62	−38	10
Cambridge	−30	−28	−10	−38	−23	9
Scotland						
Aberdeen	+22	−36	−30	− 8	−11	7
Leith	+16	−30	+ 9	−40	− 5	6
Glasgow	+21	−34	+ 3	−17	− 2	6
Ireland						
Londonderry	+37	−16	−11	+ 5	+ 4	5
Dublin	+20	−33	−46	−78	−29	8

An examination of the first column shows that during the first quarter of the year there was a deficiency of rain over the midland and south-eastern counties of England, but an excess in all other parts of the kingdom. The deficiency was most clearly marked in London and its immediate neighbourhood, where the total fall was from 28 to 30 per cent. less than the average. The excess was greatest in the north-west of England and north of Ireland; in most parts of these districts the aggregate was from 30 to 40 per cent. more than the average, but at Blackpool it was as much as 41 per cent. more.

The figures in the next column show that during the second quarter of the year the weather became much drier, and in fact a deficiency of rain was recorded over the entire kingdom. With the exception of Marlborough, where the falling off amounted to only 9 per cent., and Hereford and Londonderry, where it was respectively 19 and 16 per cent., the deficiency varied between 22 and 54 per cent., the lower value being recorded at Cirencester and the higher at York. Upon the whole it appears that the driest weather was experienced in Scotland, the north and north-west of England, and the neighbourhood of London.

From the figures in the third column it would appear that a very similar state of affairs prevailed in the July to September quarter. With the exception of Leith and Glasgow, where there was a trifling excess, every station in the table again had a deficiency of rain, the districts more seriously affected being the western and southern parts of England and the east of Ireland. In the catchment basin, from which the northern towns derive their water-supply, the deficit was not so strongly marked as in other parts of the kingdom, and the serious state of affairs which prevailed during October must therefore be set down to a long continued rather than an exceptionally severe spell of dry weather.

The figures for the month of October, given in the fourth column, show that the fall of rain was then abnormally small. At Londonderry, it is true, there was a slight excess, and at Aberdeen the deficit was not particularly striking, but in other parts of the country the falling off was very considerable. At many of the English stations the total for the month was only one-third of the average, while at Dublin it did not amount to as much as one-fourth. The places least affected were Stonyhurst, Leicester, and Cambridge, where the amount was from 29 to 39 per cent. less than the average.

The general result of all these facts, as given in the fifth column, shows that, with the exception of Londonderry, the rainfall of the past ten months has been less than the average in all parts of the kingdom. At Blackpool, Leith, and Glasgow the deficiency has not been particularly remarkable, but elsewhere, and especially in London and the home counties generally, it has been very great. At Oxford, and also in London, the aggregate fall for the period has been only about two-thirds of the average; and there is consequently no reason to doubt that, unless the weather of the remaining few weeks of 1884 undergoes a very sudden and decided change, the total for the year will be unusually small. Up to the present time (November 18) the rainfall for November has only amounted to one-third of the average for the whole month.

The last column in the table gives the number of months during which the amount of rain has been in defect of the average. At Manchester, Leicester, and Dublin there have been eight such periods, and at Cambridge nine; while at Oxford, and also in London, every month has shown a deficiency.

In endeavouring to compare the above figures with those for previous years, the meteorologist is met at the outset by a very familiar difficulty, namely that of finding reliable information for any very long period. As regards London, however, some valuable statistics are to hand in the rainfall diagram prepared some years ago by Mr. George Dines, F.R.Met.Soc. This diagram, which gives the monthly and annual fall of rain in the London district during the sixty years 1813 to 1872, was compiled with great care and precision partly from Luke Howard's observations, partly from the Cobham journals, and to a large extent from information published or supplied by Mr. Symons. By completing the statistics up to the present time, we get a long and very valuable series of returns, and are also able to obtain a really good and reliable average. In the following table are shown the

Years	For the whole year		January to October		No. of months in year with deficiency of rain
	Total fall	Percentage value below average	Total fall	Percentage value below average	
	inches		inches		
1832	19·8	20	16·4	24	9
1837	19·4	22	16·5	24	9
1840	19·4	22	15·5	28	8
1847	17·7	29	13·5	37	11
1850	19·2	23	15·8	27	9
1854	18·7	25	15·3	29	11
1858	17·3	30	15·2	30	8
1864	17·4	30	14·5	33	9
1884	—	—	13·4	38	?

total amounts of rain in London during some of the driest of the past seventy-one years, together with the percentage difference from an average based on the seventy years'

observations 1813 to 1882. In selecting the years, those only have been chosen in which the aggregate fall of rain has been at least 20 per cent. less than the average. The table further gives the total fall and difference from the average for the first ten months in each of these years, and in the last column will be found the number of months during which the rainfall has been deficient.

From the first two columns it appears that the years 1858 and 1864 claim the distinction of being the driest of all, the total falls being only 17·3 inches and 17·4 inches respectively, or 30 per cent. less than the average. Next comes 1847, with a total fall of 17·7 inches and a deficit amounting to 29 per cent. As regards the period of ten months, the present year has been drier than any of the past seventy-one, but in the year 1847 the rainfall was nearly as deficient. In the case of the other dry years the aggregate fall for the ten months was at least an inch more than in either 1847 or 1884, and in the years 1832 and 1837 it was three inches more. On comparing the returns for the past seventy-one years, one more striking fact is brought to light. Out of the whole series there has been only one occasion on which the deficiency of rain has continued through a greater number of months than it has this year. This long period of drought commenced in November 1846 and continued until November 1847, and there were consequently no fewer than thirteen consecutive months during which the rainfall in London was below the average.

FREDK. J. BRODIE

ANCIENT CHINESE GEOGRAPHY

NOT long since the Chinese Ambassador to England, in the course of a remarkable speech at Folkestone, twitted European scholars with the labours which they freely bestowed on the study of extinct nations and races, while the still existing civilisation of China, hardly inferior in antiquity to that of any other race, received but scant attention. Whether the charge is well founded or not we cannot pretend to decide here; but there is, we believe, no doubt that there is still in Chinese literature a vast mine, into which but few and trifling shafts have been sunk. The wealth of the geographical literature of China, for instance, is known to but a few scholars, and one of these, M. de Rosny of Paris, in a work recently published on the Oriental nations known to the ancient Chinese, says that, among all the literatures of the East, that of the Chinese probably contains the most valuable information for the study of Asiatic ethnography, for a crowd of nations which have disappeared, or which are unknown in Europe, have been the subject of substantial notices by the Chinese, outside which, probably, we know nothing of their political history or of the annals of their civilisation. M. de Rosny's work, which is published by the Ethnographical Society of Paris, is devoted to the translation and piecing together of extracts from old topographical works respecting various countries known to the Chinese in ancient times. Much of the labour in a work of this kind must necessarily be devoted to identifying the places mentioned. In many cases this has not even now been satisfactorily done. Thus, the origin of the name *Ta-tsin*, applied to the Roman Empire, is wrapped in obscurity. The latest theory is that it is the phonetical representation of Tarsus in Cilicia, whence Antoninus sent ambassadors to Bactria, so that the name of Tarsus was the first echo which China received of Rome. But although there is much in M. de Rosny's volume which can only interest the technical Sinologue, yet one can gather from the text, as well as from the maps, a fairly accurate idea of the knowledge of geography possessed by the Chinese in early times. Of the maps, which are nine in number, one contains the Indian Archipelago as known to the Chinese, and six others Indo-China and Malaysia, according to Chinese geographers, at various periods from the twelfth century before our era down to 906 after Christ.

The Chinese, then, according to M. de Rosny, have from the most remote times occupied themselves with the topography of the districts through which they migrated, and have studied the geography of the neighbouring countries. Yu the Great, who reigned in the basin of the Yellow River twenty-two centuries before our era, was a veritable geographer. The *Shu-king*, which contains an account of the public works executed under his direction, contains the first rudiments of Chinese ethnography, as Genesis does that of the Jews. A geographical work which is probably not less ancient is the *Shau-hai-king*. It is at least as old as the Choo dynasty—1134 B.C.—and some Chinese authors even carry its date back to the twenty-seventh century before Christ. In a book of rites of the Choo dynasty just referred to, it is stated that twenty-four officials were specially charged with the administration of a department for national geography. It is, however, to the historians that we have to look for accounts of the various peoples which early submitted to the preponderating influence of the Middle Kingdom. The nomad hordes of the north and west, and the States then in process of formation in the south, all entered into relations with the Chinese. The ambassadors whom they sent to the Court brought with them information as to the people they represented, which was duly consigned to the archives of the Empire by its historiographers. The officials sent by the Chinese in return to the peoples about them contributed their quota of geographical and ethnographical facts, until ultimately the documents on the subject became so numerous that native scholars judged it well to summarise them into one great work. It was thus that the great encyclopædia associated with the name of Ma-touan-lin was formed. Its first publication was in 1322.

The limits of the world as known to the early Chinese are stated by M. de Rosny to be: in the north, Southern Siberia and Kamchatka; in the east, the Kurile Islands, Japan, the Loochoo Archipelago, and that of the Philippines; in the south-east, Borneo and Celebes; to the south, Java, Sumatra, and Ceylon; to the west, Arabia, Persia, and the States bordering on the Caspian. Some scholars have professed to discover the Roman Empire under the name Ta-tsin, and America, which a mission of Shamans are said to have discovered in the fifth century, under that of Fousang. In the work before us the writer gives, from Ma-touan-lin and other sources, the statements of the early Chinese writers with regard to the various races inhabiting these regions; but he warns us more than once that these ancient documents, though of great value in teaching us about peoples little known to us, must be used with the utmost reserve, and only after undergoing a searching examination and criticism. The present instalment of the work deals only with the races to the south, south-east, and east, such as the Japanese, Ainos, Siamese, &c. Its value as an ethnographical and geographical work can only be known to the one or two living Europeans who have made a special study of the subject; but it places beyond doubt the fact that students of the ethnography and historical geography of the Far East will have to reckon with the works of their remote Chinese predecessors before their knowledge can be regarded as complete.

COLOUR

M. M. A. ROSENSTIEHL has made an interesting contribution to the science of colour in the form of a *brochure* recently published under the auspices of the Société Industrielle of Rouen, and entitled "Les premiers éléments de la Science de la Couleur." In this treatise, which is a model of brevity and of demonstrative clearness, the author shows that the empirical methods which have hitherto prevailed amongst colourists of all classes are radically imperfect. These methods are

based entirely upon the study of colouring-*matters*, and ignore altogether the fundamental distinction between colour as a property of such matter, and colour in the physiological sense of a particular affection of the organ of sight. It is to the study of colour by means of colour-sensations that our attention is directed; and it is to the synthesis and analysis of the retinal impressions that we are to look for exact views on the relationships of the colours. The distinction in question once stated is so obvious that the author's claim for recognition of the new system or method as the necessary complement of the older will be at once admitted. But the author's aim is not so much to obtain the intellectual assent of those accustomed to the propositions of abstract science, as rather to convince colour-artists of every denomination of the direct utility of the method—to show them, in fact, that it supplies the means of solving problems in colouring with rapidity and certainty, and furnishes valuable criteria with which to strengthen the æsthetic judgment.

The chief obstacles to the general acceptance of the method lie in the erroneous views which underlie the well-worn proverb, "Il ne faut pas disputer des gouts et des couleurs." While, in opposition to these tenets, the author contends for the admission of more positive views, and of the experimental method upon which they are based, he very distinctly disclaims the idea of substituting taste and artistic inspiration by a set of mathematical rules. "Taste," he says, "must ever remain the supreme judge of the æsthetic value of any combination of colours."

It is true that the artistic instinct confers upon its possessor a comparative independence of the methodical selection of colour; but this instinct, or intuitive perception of harmony, is by no means an unerring guide, nor without the influence of prevailing ideas. Most of these are of necessity incomplete, and many are demonstrably false: and the artistic instinct therefore needs development and correction. In the abstract which we shall give of the author's treatise, we shall give due prominence to the evidences of these shortcomings.

The elaboration of the empirical system still prevalent we owe to Chevreul. It is based entirely upon the study of colouring-matters, and its scales of colour-relationships are purely arbitrary. The theoretical treatment of colour, on the other hand, has been chiefly, and indeed necessarily, confined to the investigations of the spectrum. Early in this century, Young, the father of our modern science of light, formulated a theory of colour-sensation, a theory, that is to say, which co-ordinated the physical phenomena of coloured light with the phenomena of its appreciation by the eye. Colour, we know, is the expression of wave-length; the sense of colour was referred by Young to the agency of distinctive retinal nerves, each endowed with the capacity of selective excitation by rays of certain wave-lengths. He recognised, further, three primary divisions of wave-lengths, corresponding to red, blue, and yellow light. The later researches of Maxwell have given results confirmatory of this view, and additional testimony to the wonderful insight of this great philosopher. But we are not concerned at this moment with the theories and speculations of pure science so much as with the more practical question of the advantage to the colourist of correcting impressions derived from the empirical study of pigments, by the study of colour in the light of their main results and consequences. A very praiseworthy effort to bridge over the gap which had so long existed between the science and the art of colouring has been made by Prof. von Bezold in the publication of his work on the "Science of Colour." This excellent treatise, in spite of its translation into English, has, we think, not received the attention in this country which it deserves; this is accounted for in part by its publication in America, but an equally powerful cause is to be found in the conservatism of those to whom it appeals, in the jealousy of invasion by the forces of a new method of a territory rendered sacred by inheritance.

In both treatises considerable importance is attached to the reduction of the various terms in conventional use to the accurate expression of the ideas involved in the scientific investigation of colour. This is a task of considerable difficulty.

M. Rosenstiehl finds the French terms especially difficult to handle. The three principal substantives, *nuance*, *teinte*, and *ton*, he assigns—though with a confession that his choice is somewhat arbitrary—to the three variables respectively which determine a colour, viz. kind or quality (*espèce*), intensity, and purity. In this choice he admits that the terms *ton* and *nuance* may be said to have an inverse relationship to that which they occupy in musical language, but at the same time justifies the selection as most in accordance with present usage, pointing out, moreover, that the analogy between the ear and the eye is so slender that it is not to be sought in the terms which express their sensations. The translator of Bezold finds himself called upon to accommodate himself in his treatment of the subject to the use of the terms hue, tint, shade. To avoid prolixity we give as the result of a careful consideration of the terminology of both authors the following definitions of essential terms:—

(1) Colour in the sense of wave-length must be denominated by *hue*.

(2) The degree of brightness (French, *intensité*) we may express by *tint*.

(3) The degree of purity, *i.e.* non-admixture with white, may be rendered by *tone*.

It is obvious that (2) and (3) are, in regard to the ordinary conditions of vision, interdependent variables, for, as the intensity or illumination increases, the proportion of white increases.

It will be found on trial that, by means of these three substantives, the essential factors of any colour may be expressed. It is clear that habit will prevent our specialising the use of the word colour; but we may limit its use scientifically to the general expression of primary distinctions, reserving the term hue to indicate specially wave-length and variations in wave-length. There still remains, however, the important word *shade* to dispose of, amongst the substantives in conventional use, as well as the numerous adjectives with which they have been conjoined.

The more general use of *shade* has been to express the idea contained in (3), *i.e.* the toning of colours by addition or removal of white, and this use may be retained. At the same time, in order that our nomenclature may be precise, we must obviously avoid such expressions as a "red *shade* of orange, using instead "red-orange hue," or even "red hue of orange," or again, "dark *shade* of green," meaning thereby a green of medium tone perhaps, but of low illumination; the correct expression here would be "a green, a *dark* or *low tint*" (*couleur foncée*).

The term *couleur saturée* is applied by M. Rosenstiehl to a pure colour, or the corresponding visual sensation: such colours are obviously never met with in the arts; those which approximate to saturation he terms *couleurs franches*. These adjectives are perhaps best translated by *integral* and *full* respectively.

The spectral hues are *integral; full* colours or tones are those which give the impression of quantity of colour.

The term *gamut* or *scale* is used in two senses: first, to indicate a graduated succession of tones, *i.e.* the gradations of a given hue through its several tones to white; and second, a graduated succession of tints, or the gradations of a given hue through its several tints to black.

The *æsthetic gamut* or *scale* is the term applied by the author to graduated modifications of one and the same colour-*sensation*; its special significance will become

more apparent as we proceed in our examination of M. Rosenstiehl's work.

For the investigation of colours, or rather of colouring-matters, the author employs concentric disks, which are kept in rapid rotation by mechanical means of the simplest character. These disks may be coloured uniformly or in sectors of various hues; the well-known result of the rapid rotation is in the latter case the mixture of the sensations velvet. The admixture of black is then produced by cutting from the disk a sector; the disk being then placed before this chamber adds the sensation of black to that of colour in the proportion of the size of the sector removed to that of the disk. A special apparatus is described for measuring the sectors of the disks, as is also the very necessary instrument by which the disks are cut with or without the simultaneous removal of sectors.

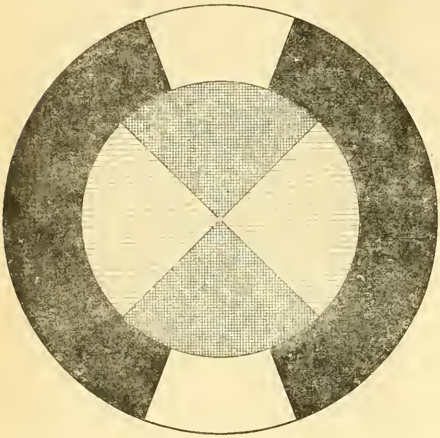

Fig. 1.

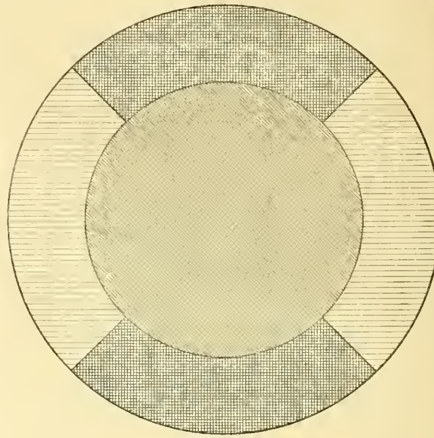

Fig. 3.

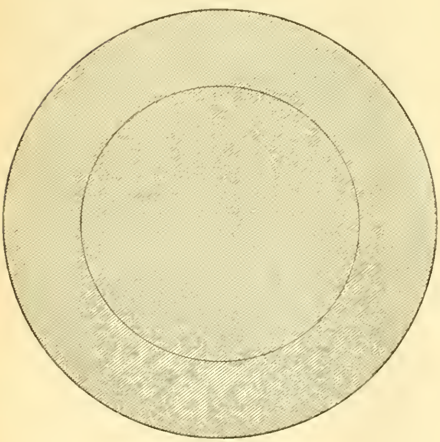

Fig. 2.

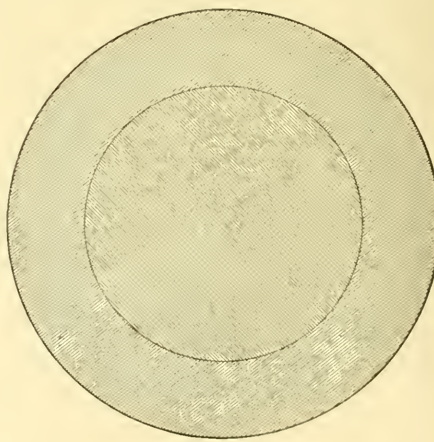

Fig. 4.

of light, then fusion into a single uniform coloured impression. In the study of the degradation of colours by admixture, it is necessary to have both a black and a white. The white is obtained by means of precipitated barium sulphate applied to a suitable surface; the black is obtained by means of a small chamber before which the disks rotate, this chamber being lined with black

The author's experimental results are given in a series of coloured plates, to which descriptive notes and explanations are attached. Some of these we proceed to reproduce. Plate I in the book is a study of complementary colours or hues. The superposed disks are represented both at rest (Fig. 1) and in motion (Fig. 2); the mechanical details, such as the attachment of the disks to the re-

volving axis, are suppressed for the sake of clearness. Under the condition of rapid rotation both disks appear to be coloured a uniform grey.

Thus in a single experiment is demonstrated (1) that blue and yellow are complementary colours, (2) that particular tones of blue and yellow produce by mixture of retinal impressions a white of low tint—in fact, by measuring the sectors composing the outer annulus, a white of 2-9ths the intensity of that of the annulus, which is produced by barium sulphate. Other binary combinations will be found to produce similar results, *e.g.* red and blue-green, violet and yellow-green. In fact given any hue, a second may be formed by means of this apparatus, such that the combination of the retinal impressions proper to each shall produce the sensation of white, the degree of this sensation varying with the tone of the constituents of the combination.

From the experimental investigation of complementary hues the definition of intensity is readily deduced. In the sectors of the plate we notice equality of area. Had we taken a fuller yellow of the same hue, the grey produced with the blue sector of equal area would have shown a yellow cast, and to restore the neutral grey or low white we must increase the area of the blue at the expense of the yellow. The relative intensity of complementary hues is thus defined to be the reverse of the sectors necessary to produce neutrality of hue.

The use of the particular yellow pigment of Fig. 1, coloured in the original chromate of lead, is dictated by the lowness of tints of all our blue pigments; the purest of our ultramarines, smalts, and aniline blues do not possess one-third the intensity of chromate of lead; and the same is true of the greens and violets.

The study of complementary colours leads directly to the discussion of the basis of this phenomenon, whether, *i.e.* it is physical or physiological? It is in this department of the subject that confusion of ideas has longest persisted. Although it was pointed out by M. Plateau as long ago as 1829 that the mixture of colouring-*matters* and of colour-*sensations* are distinct phenomena, the classical experiment of Muschenbroek, dating from 1762, is still retained by lecturers and text-books, together with erroneous interpretations. Newton himself fell into the same error in his discussion of the recombination of the spectral colours. The author puts the matter in the clearest light by pointing out that there are a number of mixtures producing the sensation of white light,—that psychological identity, therefore, is no criterion of physical identity.

The distinction is perhaps most clearly demonstrated by a plate of figures representing the superposed disks at rest and in motion. The outer annulus is composed of alternate and equal sectors of blue and yellow, the inner disk being coloured with a mixture of blue and yellow pigments in equal proportions. The distinction in appearance produced by motion affords the clearest demonstration of the point in question (Figs. 3 and 4).

The next portion of the treatise is devoted to the study of mixtures of colours, *i.e.* colour-sensations, which are not complementary. The more important results are those obtained in the so-called "degradation" of pigments. Such pigments, for instance, when applied to a white surface, will be more or less mixed with white, *i.e.* the sensations of white will be more or less conjoined with that of the pigment hue, as the quantity of pigment per unit of surface is less. The author reproduces series of such tones, in the case of Prussian blue and chrome yellow, together with their respective complementaries. In both cases it is found that the progression is accompanied by an alteration in hue, the fuller tones being distinctly redder. It is clear, therefore, that to construct a scale or gamut of tones with any given pigment, in order that this shall have an æsthetic or standard value, each tone must be referred to the same complementary, and the tones due to the pigment alone will need correction in accordance with their demonstrated imperfections, *i.e.* departures from the standards determined by the method of physiological comparison.

The author has very carefully compared such scales of tones with the purely arbitrary scales of M. Chevreul, and has found the differences to be considerable. Such indeed might be inferred indirectly from M. Chevreul's definition of "the tones of a colour"; they are, according to him, "the different degrees of intensity of which a colour is susceptible according as the *substance* by which it is produced (*représenté*) is pure or mixed with white."

A comparison of colour combinations harmonised according to the two systems, will show the æsthetic superiority of the physiological method, judged, that is, by the much abused arbiter, *taste*. It is unnecessary further to insist upon the practical importance of such conclusions. It will doubtless have been already appreciated on the part of the reader that the confusion of ideas which it is the object of this treatise to eliminate cannot have remained without influence upon the education of the eye; nor can he fail to see that the training involved in the practice of the author's experimental method is a valuable æsthetic discipline, as well as a precise study of colour relationships.

We have attempted to give an idea of the difference in appearance of the disks by lines on a white surface.

THE LATE FERDINAND VON HOCHSTETTER

THE numerous friends and admirers of the late Dr. Ferdinand von Hochstetter in Europe and Australasia have to thank his old associate, Dr. Julius von Haast, for a graceful tribute paid to his memory, which takes the form of a sympathetic biographical notice published towards the end of last August at Christchurch, New Zealand. The memoir, which is accompanied by two portraits, from a lithograph and a photograph showing the distinguished naturalist in his twenty-ninth and fiftieth years respectively, is taken for his early career partly from an account in Brockhaus's "Conversations Lexicon," and for the period since the two friends first met at Auckland, N.Z., in 1858, from Hochstetter's writings and private correspondence. Born on April 30, 1829, at Esslingen, Wurtemberg, the future naturalist was at first intended for the Church by his father, Prof. Christian Ferdinand Hochstetter, chief pastor of that town, and himself a botanist of no mean repute. But in the seminary of Maulbronn near Tübingen, his love of science, implanted in the paternal home, grew so strong that, besides theology, he applied himself with great zeal to the study of mineralogy, palæontology, and geology. After taking his degree of Doctor Philosophiæ in 1852 he seems to have finally made choice of a scientific career, and in 1853 found employment on the Geological Survey of the Austrian Empire, soon after receiving the appointment of Chief Geologist for the Bohemian Section. His reports on the geology of the Boehmer Wald were so highly appreciated that he was selected in 1857 as geologist of the *Novara* Expedition, which brought him to Auckland on December 22, 1858. Here his services were at once secured by the Government, and with the reluctant consent of the Commodore of the *Novara* he accepted an engagement of eight months to examine the geology, physical features, and natural history of New Zealand. During this period he made extensive topographical and geological surveys of the provinces of Auckland and Nelson, the results of which were embodied in his standard work, "Neu Seeland," published in 1863, followed in 1867 by the greatly enlarged English edition dedicated to the Queen. Soon after his return to Europe he was appointed Professor of Geology and Mineralogy in the Technical University of Vienna, and after a visit of some months to England in 1860 he settled permanently in the Austrian capital, where, in April 1861, he married

Georgina Bengough, daughter of the English director of the Vienna gas-works. A visit in 1863 to Vesuvius was followed next year by the appearance of the "Geology of New Zealand" and of the "Palæontology of New Zealand," both of great scientific value, and forming his main contributions to the extensive series of the *Novara* publications.

About the same time Hochstetter was commissioned to explore the lacustrine basins in Carinthia and other parts of Austria, where he discovered numerous remains of kitchen-middens and prehistoric lake dwellings similar to those found in the lakes of Switzerland. In 1867 he was elected President of the Imperial Geographical Society of Vienna, a position which he held till compelled by his failing health to resign it in 1882. He now commenced the publication of a whole series of geological and mineralogical text-books for higher schools, which were introduced into many parts of the Austrian Empire, and one of which, on crystallography, was especially distinguished by its clearness and thorough grasp of the subject. Time was now also found to complete his geological essays on the Cape of Good Hope, the Island of St. Paul, the Nicobars, and Java, for the *Novara* series, and also to publish an interesting account of the great earthquake and sea-wave of 1868, in the southern hemisphere, including a calculation of the mean depth of the Pacific deduced from the known velocity of the waves across that ocean. The appointment of Consulting Geologist to the Turkish Great Railway Company brought him in 1869 to the Balkan Peninsula, the results of which journey soon after appeared, partly in the *Proceedings* of the Vienna Geographical Society, partly in the *Year-Book* of the Imperial Geological Institute, and in *Petermann's Mittheilungen*. For these important geological surveys he was decorated by the Sultan with the order of the Mejidié. Notwithstanding the loss of his eldest daughter Julia in 1871, and a chronic affection of the throat, his scientific writings and surveys were now continued with unflagging zeal, including a handbook of geology which formed part of the "Allgemeine Erdkunde"; an atlas of twenty-four geological pictorial views, with letterpress; much harassing work in connection with the Viennese International Exhibition of 1873; and lastly, an arduous journey of over two months in the summer of 1872 to the Urals and Siberia as consulting geologist to a large mining association. Then came his honourable appointment as teacher of science to Crown Prince Rudolph in 1872, followed in 1875 by his election to the Rectorship of the Technical University, and in 1876 to the position of Imperial Intendant (Chief Curator) of the Imperial Austrian Museum of Zoology, Ethnology, and Natural History. He had hoped to witness the completion of this magnificent building, which has been in progress for many years; but, although it was nearly ready for occupation as early as the summer of 1881, he did not live to see it opened to the public. In the interests of the Museum he visited Denmark, Holland, Belgium, and North Germany in 1876, and was soon after busily engaged superintending excavations in Carinthia, Bohemia, and other parts of the empire, which resulted in the discovery of rich palæontological and archæological treasures, prehistoric burial-places, skeletons of the extinct cave bear, remains of fossil man, a large number of bronze ornaments, weapons, and implements. Towards the end of 1879 his health began to decline. He suffered much about this time from pains in the legs and arms, accompanied by sleeplessness and other symptoms which later developed into an incurable attack of diabetes, terminating on July 21 last a laborious and blameless life devoted entirely to the advancement of the natural sciences. Indefatigable to the last, he found time in the midst of his multifarious labours to issue a report in 1883 on some Mexican antiquities discovered by him in the Ambrose Collection in Tyrol, and which had originally been sent by Fernando Cortez to the Emperor Charles the Fifth. His last contribution to science was a paper read in February of the present year before the Vienna Geological Institute, giving an instructive account of the celebrated mineralogical collection now removed to the New Imperial Museum. Hochstetter's life may thus be described as an epitome of the history of the natural sciences in Austria during the last quarter of a century. Dr. von Haast's appreciative memoir concludes with the appropriate lines from Goethe:—

> "Fest steh' dein Sarg in wohlgegönnter Ruh;
> Mit lockrer Erde deckt ihn leise zu,
> Und sanfter als des Lebens, liege dann
> Auf dir des Grabes Bürde, guter Mann!"

NOTES

PROF. G. H. DARWIN, of Cambridge, and Prof. Daniel Oliver, of the Royal Gardens, Kew, have been nominated by the Council of the Royal Society for the award of the two Royal Medals conferred by the Crown. The Copley Medal is to be given to Prof. Carl Ludwig, of Leipzig, in recognition of the great services which he has rendered to physiological science. Prof. Tobias Robertus Thalén, of Upsala, is to have the Rumford Medal for his spectroscopic researches; and the Davy Medal is awarded to Prof. A. W. H. Kolbe, also of Leipzig, for his researches in the isomerism of alcohols. The two Leipzig Professors are Foreign Members of the Society. Prof. Darwin and Prof. Oliver are Fellows, the former well known for his mathematical investigations on the rigidity of the earth and on tides, the latter for his investigation of the classification of plants and for the important services which he has rendered to taxonomic botany.

IN speaking recently at the Academy of Music in Philadelphia to a large audience on the wave-theory of light, Sir William Thomson made the following remarks on the employment of the metrical system:—"You, in this country, are subjected to the British insularity in weights and measures; you use the foot, and inch, and yard. I am obliged to use that system, but I apologise to you for doing so, because it is so inconvenient, and I hope all Americans will do everything in their power to introduce the French metrical system. I hope the evil action performed by an English Minister whose name I need not mention, because I do not wish to throw obloquy on any one, may be remedied. He abrogated a useful rule, which for a short time was followed, and which I hope will soon be again enjoined, that the French metrical system be taught in all our national schools. I do not know how it is in America. The school system seems to be very admirable, and I hope the teaching of the metrical system will not be let slip in the American schools any more than the use of the globes. I say this seriously. I do not think any one knows how seriously I speak of it. I look upon our English system as a wickedly brain-destroying piece of bondage under which we suffer. The reason why we continue to use it is the imaginary difficulty of making a change and nothing else; but I do not think in America that any such difficulty should stand in the way of adopting so splendidly useful a reform."

IT is stated that Lord Rayleigh has resigned the Cavendish Professorship of Experimental Physics. The electors are Sir W. Thomson, Sir William (Justice) Grove, Profs. Liveing, Stokes, Darwin, R. B. Clifton (Oxford), and Stuart, and Mr. W. D. Niven.

DR. THOMAS WRIGHT, F.R.S., of Cheltenham, died on the night of Monday last. This sad announcement will be received with much regret by all who take interest in the progress of geology and palæontology. We hope to give some account of the deceased naturalist next week.

THE presentation of prizes and certificates to the students of the Finsbury Technical College, and of the South London School of Technical Art, and also to the candidates at the Technological Examinations held this year in London will take place at the Fishmongers' Hall on the 4th proximo at 7.30 p.m. The Lord Mayor will preside, and the prizes will be presented by the Lord Chancellor.

NEWS from Japan states that Prof. Milne, of Tokio University, is about to establish a subterranean observatory at Jacashima, a very deep coal-mine not far from Nagasaki. The object of this observatory is to determine what connection exists between the earthquake phenomena and meteorological phenomena belonging to the earth's surface, such as storms, barometrical pressure, tides, tidal waves, &c.

M. HANSEN-BLANGSTED contributes to *L'Exploration* an interesting article on the struggle between trees in the Danish forests. The chief combatants are the beech and the birch, the former being everywhere successful in its invasions. The paper refers especially to the district of Silkeborg in the heart of Jutland. Forests composed wholly of birch are now only found in sterile sandy tracts; everywhere else the trees are mixed, and wherever the soil is favourable the beech rapidly drives out the birch. The latter loses its branches at the touch of the beech, and devotes all its strength to its upper part, where it towers above the beech. It may live long in this way, but it succumbs ultimately in the fight—of old age if of nothing else, for the life of the birch in Denmark is shorter than that of the beech. The writer believes that light is the cause of the superiority of the latter, for it has a greater development of its branches than the birch, which is more open, and thus allows the rays of the sun to pass through to the soil below, while the tufted, bushy top of the beech retains them, and thus preserves a deep shade at its base. Hardly any young plants can grow under the beech except its own shoots; and while the beech can flourish under the shade of the birch, the latter dies immediately under the beech. The birch has only been saved from total extermination by the facts that it had possession of the Danish forests long before the beech ever reached that country, and that certain districts are unfavourable to the growth of the latter. But wherever the soil has been enriched by the decomposition of the leaves of the birch the battle begins. The birch still flourishes on the borders of lakes and other marshy places, where its enemy cannot exist. In the same way in the forests of Zeeland the fir forests are disappearing before the beech. Left to themselves the firs are soon replaced by the beech. The struggle between the latter and the oak is longer and more stubborn, for the branches and foliage of the oak are thicker, and offer much resistance to the passage of light. The oak also has great longevity, but sooner or later it, too, succumbs, because it cannot develop in the shadow of the beech. The earliest forests of Denmark were mainly composed of aspens, with which the birch was apparently associated; gradually the soil was raised and the climate grew milder; then the fir grew and formed large forests. This tree ruled for centuries, and then ceded the first place to the holm oak, which is now giving way to the beech. Aspen, birch, fir, oak, and beech appear to be the steps in the struggle for the survival of the fittest among the forest trees of Denmark.

WE learn from *Science* that the U.S. Signal Service is about to undertake the publication of a general bibliography of meteorology and allied topics (such as earthquakes, terrestrial magnetism, and meteors), and requests from the writers of all countries a complete list of their contributions to the literature of these subjects, including the titles of all separate works, papers, and published observations. The number of titles already on hand is about 35,000. Especial attention is invited to the importance of full titles, with details of size, and place and date of publication. References to periodicals should be on this pattern:—

"Quetelet, Lambert Adolphe Jacques,
Sur les orages du mois d'Avril, 1865.
Bruxelles, *Acad. Sci. Bull.* XIX., 1865, 535-537."

Correspondence should be addressed to the Chief Signal Officer, U.S. Army, Washington.

ERMANNO LOESCHER of Turin has just issued the fifty-first catalogue of the literary treasures contained in his "Libreria Antiquaria." The present number is devoted chiefly to geography, travel, and antiquities, and the contents are conveniently arranged under four heads: America, Africa, China with Japan, Geography and Travels. Amongst the entries, which number 429 altogether, the bibliophile will find much to interest him.

HERR J. OLSEN, a Norwegian botanist, who has been studying the fungi in the vicinity of Bergen during the summer, has found a *Gomphidius gracilis* at Hovland. This variety has never before been found in Scandinavia, and belongs to England. Of other varieties new to Norway which he has discovered may be mentioned *Rhizopogon luteolus* and a *Boletus*. The flora of Tysnæs Island is stated to be identical with that of England.

THE following letter has been received by Prof. E. Ray Lankester, F.R.S., the Secretary of the Marine Biological Association, announcing a donation from the Royal Society in aid of the fund (now approaching 5000*l.*) which is being raised for the purpose of building and fitting a marine laboratory and experimental aquarium at Plymouth:—"Royal Society, Burlington House, London, W., Nov. 1, 1884. Sir,—Your letter relative to the Marine Biological Association was laid before the Council at their meeting on Thursday last, and I am directed to inform you that the Council have voted the sum of 250*l.* from the 'Donation Fund' in aid of the 'Marine Biological Association,' as a token of their sympathy with an effort which, they have every reason to believe, will contribute largely to the progress of biological science in this country.—I beg to remain, yours obediently, M. FOSTER, Sec.R.S."

AMONG other interesting papers in the *Proceedings* of the Perthshire Society of Natural Science for 1883-84 we notice: dimorphism in oak-gall makers and in their galls, by Prof. J. W. Trail, F.L.S.; evolution and some things said regarding it, by Rev. G. Milroy, D.D., in which a "creative" and "spontaneous" view of the origin of life is discussed with studied dispassionateness. We are glad to observe the flourishing state in which this Society seems to be.

PROF. DE LACOUPERIE is bringing to a conclusion a work on the aboriginal and non-Chinese races of China, which will be published shortly by Messrs. Field and Tuer. It will deal with one section of the learned author's researches into the *origines Sinicæ*, in which he has been engaged for several years, and which have been so successful in some important respects. One of the most curious results of the work will be to demonstrate the real youth of the Chinese as a homogeneous and powerful people. It is based wholly on original researches into Chinese literature, and this is, we believe, the first time that the ethnology of early China has been studied from the works of the Chinese themselves, or indeed at all. The work deals with the various tribes which have successively occupied China proper, and which are intimately connected with the Indo-Chinese races, the latter being in fact the modern representatives of the early occupants of China. The originality of the subject, as well as of the sources from which it is treated, should render the volume one of great scientific and general interest. The work was originally prepared as an introduction to Mr. Colquhoun's new book "Among the Shans," but it gradually

grew to such an extent under its author's hands that it became too large for such a purpose, and this, as well as its independent value, rendered it desirable to have a separate publication. Mr. Colquhoun's volume, which is on the point of publication, will, however, contain an introduction by Prof. de Lacouperie on the cradle of the Shan race, which, curiously enough, he places far away on the borders of Shensi.

Prof. Enrico Caporali continues to develop the scheme formulated in the first number of *La Nuova Scienza* with great vigour and learning. The third number, for the quarter ending September 1884, shows even greater energy and grasp of the subject than its predecessors. The editor's views are now quite clear—opposition alike to the two extremes of materialism and dogmatism, and the establishment of a new philosophy reconciling the subjective methods of the old schools with the objective standpoint of the new. Evolution in the Darwinian sense is accepted without reserve, and the germs of life are sought in the very lowest forms of matter—the crystal, the molecule, and the atom itself. Thus evolution receives its broadest expression, and begins from the very first as well for the vital force as for crude matter itself. The first genesis of psychis is in fact referred to a unity arising out of the fusion of lower chemical species in a higher chemical species, which forms the connecting link between *chemical* and biological psychogenesis. In it individuals begin to react in such a way that the opposition between subject and object may almost be said to have already begun. The theory is ingenions and skilfully worked out; but the unusual interest taken on the Continent in this periodical is probably due mainly to the remarkable learning, clearness, and consistency with which the editor's views are advocated. In the present number the chief articles are: —Modern Italian Thought, the Pythagoric Formula of Cosmic Evolution, and the French Anti-Clerical Evolution.

A high-level meteorological station has been recently established by Mr. Wragge on Mount Lofty, about 2200 feet high, and ten miles from Adelaide, South Australia. With Mr. Wragge's great energy and ability valuable results will doubtless be obtained from this new high-level station in connection with the excellent meteorological service of the colony.

In the Report on Weights and Measures presented to Parliament by the Board of Trade, under the Weights and Measures Act, 1878, Sir T. H. Farrer remarks in reference to the metric system, that an opinion has been expressed by the Board of Trade that the time has now arrived when this country might with advantage join the International Convention on Metric Standards, under proper conditions; provided such a course is not to be taken as an adhesion, on the part of the United Kingdom, to the metric system. These observations appear to be intended as a reply to the eighth resolution of the Conference of the International Geodetical Association, held in Rome in October last, which expresses a hope that, if the rest of the world accepts the meridian of Greenwich for the unification of longitude, England will find in this agreement an additional motive for taking a new step in favour of the unification of weights and measures, by adhering to the Metrical Convention of May 20, 1875.

Two years ago Prof. O. Sars, of Christiania, was given some mud taken from the bottom of a lake in Australia by Dr. Lumholtz, a Norwegian geologist. Recently he has made experiments with the same in small aquaria, and has succeeded in producing from the dried mud quite a fauna of Australian freshwater invertebrates.

According to *L'Exploration*, Commander de Amezaga, of the Italian navy, has handed to the Ministry of Marine at Rome the collections made during the recent voyage of the corvette *Carracciolo*. The voyage lasted more than two years and a half, during which time she touched at Montevideo, Valparaiso, Callao, Guayaquil, Sydney, Singapore, and Aden. Important hydrographical investigations were made in the Straits of Magellan and on the coasts of Fiji, Tahiti, and among the islands of the South Pacific. The collections relate principally to anthropology, ethnology, the fauna and flora of Peru and Australia, Peruvian pottery, mineralogy, and zoology. In the Anthropological Section there are three Peruvian mummies in perfect preservation, although they probably date back a thousand years before the Spanish Conquest. They are distinguished from the Egyptian mummies by being in a crouching position instead of at full length. In the Ethnological Section there is a curious specimen of Carib art found at the summit of Mont Cristi, near Guayaquil.

The *Times* announces the death of the celebrated naturalist and traveller, Dr. Alfred Brehm, in his fifty-fifth year. The son of a Thuringian ornithologist, he devoted much of his own attention to the study of birds, but all animal nature was his province, and his observations and researches are recorded in volumes of high importance and value. While still a very young man he spent several years in the north-east districts of Africa, and later in life undertook frequent scientific tours in distant lands, including a visit to Siberia and Turkestan. In 1862 he accompanied the Duke of Coburg-Gotha to Abyssinia, and in 1877 acted as scientific guide to Prince Rudolph in the country of the Danube. The deceased was for some years Director of the Zoological Gardens at Hamburg.

A magnificent meteor was observed at Mülheim, on the Rhine, on the evening of October 30 last. Its direction was from north-east to south-west, its duration two to three seconds. While visible its progress was accompanied by a hissing sound, and it finally exploded with a loud report and brilliant blue-reddish light, leaving a bright trail behind which was still visible half a minute later.

Two prehistoric tombs have been recently opened near the villages of Latdorf and Gröna near Bernburg (Germany), under the direction of Prof. Virchow. Three skeletons, an urn, a comb, a bronze ring, a flint knife, and half a horseshoe were found. The excavations have now been continued under Dr. Fischer's direction, and more objects brought to light, among others curious necklaces made of the teeth of bears, wolves, and foxes. The age of the tombs is said to be over 3000 years. The objects found will be preserved in the museum of the Bernburg Antiquarian Society.

We have received from Mr. Henry Simon, of Manchester, a copy of a pamphlet by Mr. Breckon, Mr. Simon's representative for the Cleveland district, on the question of the manufacture of metallurgical coke in connection with the saving of the by-products. An account of the present position of the question in England is added, as well as a reprint of papers on the subject read by Mr. Simon, Mr. Dixon, and Mr. Smith before the Iron and Steel Institute and the British Association.

The tobacco plantations of Southern Hungary are threatened by a terrible pest, viz. the so-called wire-worm, which differs from the ordinary tobacco-worm, inasmuch as it enters the stem of the plant just above the root and then works its destructive way right up to the flowers. Plants thus attacked yield no tobacco whatever, as the leaves turn yellow and fall shortly after the worm has attacked the stem. The tobacco-worm merely attacks the root. The large plantations of Maslak, which are celebrated for their excellent produce, have been nearly all destroyed this year by the wire-worm, while in other districts the tobacco-worm has done much damage.

A LARGE Horticultural Exhibition is to be held at Berlin in September 1885.

A COFFEE plantation has been established by a landowner in the neighbourhood of Rome. It is stated that he realised a fair profit with this year's harvest, which consisted of 2 tons of coffee per hectare.

A NEW mud-crater has formed at the foot of Mount Etna, measuring some 500 metres in diameter. The mud ejected by it flows towards Monte Furmento and the pine forest of Biancavilla.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii* ♀) from South Africa, presented by Mr. J. A. Cameron; an Asiatic Wild Ass (*Equus onager* ♂) from South-Western Asia, presented by Lieut.-Col. R. A. Crawford; a Short-eared Owl (*Asio brachyotus*), a Lesser Kestrel (*Tinnunculus cenchris*) from Griqualand West, South Africa, presented by Mrs. L. Weil; a Common Cormorant (*Phalacrocorax carbo*), British, presented by Mr. S. S. Mossop; a Macaque Monkey (*Macacus cynomolgus*) from India, deposited; two Tasmanian Wolves (*Thylacinus cynocephalus*) from Tasmania, a Reindeer (*Rangifer tarandus* ♂) from Labrador, a Golden-winged Woodpecker (*Colaptes auratus*) from North America, a South American Rat Snake (*Spilotes variabilis*) from South America, purchased.

OUR ASTRONOMICAL COLUMN

THE SATURNIAN SYSTEM.—Dr. W. Meyer, late Assistant Astronomer at the Observatory of Geneva, has published in t. xxix. of *Mémoires de la Société de Physique et d'Histoire Naturelle de Genève* a determination of the dimensions of Saturn's rings and of the orbits of six satellites, and the mass of the planet, founded upon observations made at the Observatory, with a filar-micrometer on the Merz refractor of 10 inches aperture, presented to that institution by the late Prof. Plantamour. The observations in question were made during the opposition of 1881, and upon a system which it was believed would give the measures a superiority over those obtained with the same instrument in the previous year. The memoir on Saturn and his satellites, which has been separately published, is preceded by a very minute description of the Plantamour equatorial by Prof. Thury. The measures are printed in detail with the elements of reduction employed; they extend from August 15 to December 19. Dr. Meyer considers that Mimas was certainly observed on five nights, though he remarks: "Même dans la colossale lunette de Vienne, c'est un objet très délicat, qui est rarement visible quand il n'est pas près d'une élongation." On November 4, at 10h. 31m., a very faint object was observed, approximately in the position—$x = 254''$, $y = -35''$, which, by means of Prof. Asaph Hall's ephemeris, Dr. Meyer identifies as Hyperion. In the discussion of the orbits of the satellites (Enceladus, Tethys, Dione, Rhea, Titan, and Japetus) provisional elements are assumed, and are corrected in the usual manner by equations of condition. In order to determine the mean motions, the Geneva results are compared with those of Bessel in the case of Titan, while for other satellites the comparison is made with the epochs deduced by Jacob from his measures at Madras in the years 1856–58, it being considered that, in view of the precision attaching to them, little would be gained by having recourse to the older observations, especially as difficulties attend their explanation in many cases.

The mass of the ring is concluded to be very minute, certainly very much less than the value assigned by Bessel; it is stated that with the aid of Tisserand's theory, taken in connection with the results of observation, $\frac{1}{1647}$ was found for a higher limit. The most probable mass of the planet deducible from the Geneva observations is $\frac{1}{3482\cdot5}$, agreeing within the probable error with that assigned by Jacob, and that derived by Prof. Asaph Hall from the Washington measures of Japetus.

The following are the periods of the satellites and their mean distances from Saturn, determined by Dr. Meyer:—

	Sidereal revolution d. h. m. s.	Mean distance In arc ″	In equatorial radii of Saturn
Enceladus ...	1 8 53 6·92 ...	34·350 ...	3·866
Tethys ...	1 21 18 25·62 ..	42·751 ...	4·812
Dione	2 17 41 9·29 ...	54·757 ...	6·163
Rhea	4 12 25 11·57 ...	76·484 ...	8·608
Titan	15 22 41 23·16 ...	176·910 ...	19·911
Japetus ...	79 7 49 24·84 ...	514·711 ...	57·930

THE VARIABLE STAR U GEMINORUM.—Mr. Knott has succeeded in observing another maximum of this irregular variable, which appears to have taken place on October 22, though there was very little change for four days after that date. On October 18 it was below 13·3 m. From his previous observations compared with this one, Mr. Knott infers that there has been a double period in 160 days.

ENCKE'S COMET.—M. Otto Struve has notified that an ephemeris of this comet, extending from the beginning of the present month to the beginning of May next, has been prepared by Dr. Backlund, and that it was intended to communicate it to astronomers direct from Pulkowa.

WOLF'S COMET.—M. Gonnessiat, of the Observatory at Lyons, has calculated elements of this comet from observations extending over forty-five days: he finds the period of revolution 6·862 years. The following ephemeris is deduced from his orbit:—

At Paris Midnight

	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth	Intensity of light
November 21	22 57 13	93 6·0	0·0035	0·74
23	23 2 11	93 31·4		
25	23 7 11	93 54·9	0·0169	0·70
27	23 12 13	94 16·4		
29	23 17 18	94 36·0	0·0300	0·65
December 1	23 22 23	94 53·8		
3	23 27 30	95 9·8	0·0425	0·61

The intensity of light on September 21 is taken as unity.

GEOGRAPHICAL NOTES

AT the last meeting of the French Geographical Society Dr. Paul Heis read a paper upon the results of his journey through the valley of the Meikong, and further north into the unexplored region which separates Indo-China, properly so-called, from Tonquin. Dr. Heis has made several discoveries likely to be of service to anthropologists, geologists, and mineralogists, and has brought back with him a collection of insects and reptiles, as well as a meteorological register, which was checked four times a day during the whole of his journey. Leaving Saigon on December 12, 1882, he ascended the Meikong as far as the 18th parallel, at which point he turned off from the main stream in order to go up its affluent, the Nancham, and endeavoured to reach Luang-Prabang through the hitherto unexplored region known in Annam as the principality of Tranninh. This region is infested by Chinese brigands, called Hos, who drove him back to the Meikong, and seized the greater part of his baggage. Reascending the river to Luang-Prabang he remained there for eight months, exploring the country in various directions, notably along the Nancham, which took him close to the region of the Hos, so that he was again compelled to retrace his steps. Being prevented from returning eastward, he went through the Siamese part of Burmah, reascended the Meikong as far as Chieng-sen, thence, passing from the basin of the Meikong to that of the Meinam, he reached Chieng-mai, and so made his way on foot to Bangkok, following the course of the Meinam. From Bangkok he went to Chantalun, on the west coast of Siam, and thence on foot to Baltambang, traversing the plain of the Saphyrs, where 4000 Burmese are employed in the search for precious stones. After visiting the ruins of Angkor, he reached Saigon on June 12 last.

THE oldest Geographical Society in Europe has hitherto been regarded as that of Paris, founded in 1821, but according to a paper recently read before the Verein für Erdkunde at Dresden by Dr. Ruge, this honour belongs to the "Cosmographic Society" of Nuremberg. It was established about 1740, and first came before the public in 1746, and was connected with Homann's establishment in Nuremberg. The founder of the latter was the well-known cartographer, Johann Homann, on

whose death in 1724 it descended to his son. The latter, having died childless, gave the business to a relative named Ebersberger, and a friend named Franz, provided they always retained the name of Homann in the title of the firm. Franz endeavoured to introduce originality into their maps, thus coming in contact with many geographers, and ultimately founding the "Cosmographic Society," which was divided into mathematical, geographical, and historical sections. In a work published in 1750—the "Kosmographische Nachricht und Sammlung auf das Jahr 1748"—the Society complained loudly of the defective condition of mapping and surveys in the German States, and criticised unfavourably existing maps of Germany, as well as suggested the best modes of improving them. The paper then describes the principal members of the Society, their projects for the increase of geographical knowledge—among others a lottery to procure funds. Gradually, however, the leading spirits were called away to various German universities, or to Russia; the Seven Years' War prevented any steady work of the kind advocated; Franz and Tobias Meyer died, and the "Cosmographic Society" ceased. Its labours appear to have been confined to remedying defects which lay at hand, to supplying good popular maps of Germany, and to obtaining more accurate information as to German geography.

In August last the ship *Fenorina*, Capt. Nilson, arrived at Philadelphia from Ivigtut, in Greenland, reporting that an Eskimo had found on an ice-floe in the Julianehaab Bay, the lower part of a tent, the sides of a wooden chest, and some other things marked *Jeannette*, a bill of lading, and some cheques signed "De Long," a pair of oilskin trousers marked "Louis Noros," and a bearskin which covered something of the shape and size of a human body, but which the Eskimo did not examine on account of his superstitious prejudices. On another floe he found a quantity of sailors' apparel. The Eskimo brought some of the articles to Julianehaab, and gave them to the governor, Herr Lytzen, who at once set out to recover all the rest, but the Eskimo was unable to find the spot again. Herr Lytzen now states that among the articles are two sides of a wooden chest, on which is written in pencil, "General orders, telegrams, sailing orders, discipline, ship's papers, various papers, various agreements, charter party, . . ." The last words are not very clear. On the other board is written, "Before sailing." There is also a torn book of cheques, on which is printed, "For deposit with the Bank of California," and a pair of oilskin trousers marked "Louis Noros." The most remarkable circumstance of this discovery is naturally the spot in which it was made, as these articles must in the course of three years have drifted on an ice-floe from long. 155° E. to 46° W.! They can hardly hail from the place where the *Jeannette* was crushed, as she sank, and the surrounding ice-floes were ground to dust by the catastrophe. But we know from the reports of Messrs. Dannenhower and Melville that the crew, after leaving the vessel, camped for a few days on some ice-floes, in order to divide the provisions. This took place near the New Siberian Islands, and probably the tent had been erected where the remains were now found. As nobody had then died, there cannot have been any corpse under the bearskin. Which way the ice-floe has drifted can only be conjectured; but by a rough calculation the distance is about 2500 nautical miles, and, as it has been covered in about 1000 days, the average rate of drifting is 2½ nautical miles per day, without allowing for deviations.

"Emperor William," "Prince Bismarck," and "Count Moltke" are the names given to three cataracts by Herr Gustav Mederstein on his exploring tour up the Parana River in the province of Misiones (Argentine Republic). They belong to a middle group of some hundred cataracts of the Iguassi River, which at that spot forms the boundary between the Argentine Republic and Brazil. The river's breadth above the falls is about 5 kilometres; the "Emperor William" is the middle one of the three cataracts, and the total height of the falls is about 50 metres. At a distance of some 16 kilometres below the falls the Iguassi joins the Parana.

M. Thouar, who has already travelled in South America in search of the Crevaux Expedition, is about to commence a new journey of exploration, which is to last two or three years. He intends investigating the delta of the Pilcomayo, and endeavouring to open a great trade route between Bolivia and Paraguay. In this work he will, it is said, receive the active support of several South American Governments. During the journey he will collect the materials for a great work on South America.

The Expedition which had left Loango, led by Lieut. Delizie, in order to carry provisions to De Brazza's Mission at Stanley Pool, was abandoned by about two hundred carriers on the shore of Lake Loudima. It arrived at the Manyanga Station on the Congo (a station of the International Society) on July 18, and prepared to make a new start.

AN ACCOUNT OF SOME PRELIMINARY EXPERIMENTS WITH BIRAM'S ANEMOMETERS ATTACHED TO KITE STRINGS OR WIRES[1]

These experiments were regularly commenced in September 1883, and continued at intervals up to June 14, 1884. A preliminary note descriptive of the apparatus and method employed appeared in the *Quarterly Journal* of the Royal Meteorological Society in 1883. As, however, some improvements have since then been made in the mode of flying and estimating the heights, it may be as well to give a brief account of the scheme *de novo*.

First of all two kites are now flown tandem, the upper one being a small kite about 4 feet high, which is easily got up, and which, when it has reached an altitude of about 100 feet, where the wind is always considerably stronger than at the earth's surface, is used to lift up the larger main kite (7 feet high) which bears the string (latterly wire) to which the instruments are fastened. It also helps to keep the latter steady when up, and prevent any sudden and dangerous descent of kites and instruments. The larger kite is now made of tussore silk of the diamond pattern and capable of folding up like Archer's patent portable kites. The tail, which is in reality a most important adjunct, and usually the first part of the apparatus to give way, is made of six large wire-rimmed canvas cones fastened to a swivel which allows them to revolve without twisting their cord.

In the first experiments the main kite was flown with a strong flax cord, but latterly, at a suggestion by Sir William Thomson, piano-cord steel wire has been used similar to that employed in Sir William's deep-sea sounder. This I have found a great improvement on the string. It is double the strength, one-fourth the weight, one-tenth the section, and one-half the cost, the only drawback being that, unless great care be exercised, it is very liable to kink and rust. To obviate the latter I have got my supply for the coming year electroplated.

It is also necessary to have wire all through, otherwise a disagreeable discharge of electricity is apt to take place at the junction of the wire and string in ordinary weather, a fact to which some of my friends would be able to testify. When the wire is continuous, and in contact with the iron of the winder which is riveted to the ground, I have found no perceptible shock in ordinary weather. The winder was made for me by Messrs. Elliott Bros., and though by no means perfect, is capable of being riveted to the earth so as to hold the kite in a powerful wind, and being furnished with a ratchet and spring catch, can be locked so as to allow me to attend to the anemometers, take observations with the theodolite, &c.

The anemometers are of the ordinary Biram pattern, 6 inches in diameter, and suspended to a gun-metal rod so as to swing in the vertical plane of the wire, the rod being fastened to the wire by clamps at its ends. When the large kite is about 100 feet or so from the winder, and steady, an anemometer is fastened to the nearest 100-foot mark and its indication and the time noted. The wire is then payed out a certain distance, and another anemometer attached, and so on, the interval between the lowest instrument and the winder being regulated by whether the differences of velocity are required for a comparatively high or low altitude respectively. The altitudes are measured by taking the vertical angles of the instruments every ten minutes with a theodolite placed at the winder, and combining their average value for the whole period with the lengths up to each instrument. The method employed is necessarily approximate, as I cannot leave the winder very well and take simultaneous observations at the ends of a base line. It is, however, one which I have reason to believe to be very fairly accurate. A certain allowance for curvature is made up to the lowest instrument. The arc between the two instruments is then taken to be approximately equal to its chord, and from this and the vertical angles the chord to the highest instrument is calculated, and thence its vertical height. This method

[1] Paper read at the Montreal meeting of the British Association by Prof. E. Douglas Archibald.

has occasionally been checked by observations taken at the ends of a base of 891 feet, and with such satisfactory results, that in the present case, where the observations being relative, great accuracy in measuring the absolute heights is not required, I have decided to adopt it in preference to the latter infinitely more cumbrous method.

Numerous observations have been made without success, accidents of all kinds happening both to kites and instruments, sufficient to deter any one who was not imbued with a little faith that all would eventually come right. I have therefore only been able so far to collect the results of a select few, viz. 23 in all, in which the conditions were favourable.

Hitherto I have only used kites as a *point d'appui* for observations on the differential velocity of the air at different heights, a purpose for which they are obviously exceptionally fitted. I am hoping, however, during the coming year, with new and improved apparatus and assistance, for which I have received a Government grant, to employ the same means of elevation for observations of temperature, pressure, height of cloud-strata, &c.

The height of the place of observation is 500 feet above sea-level.

Of course it is not intended at this early stage to attempt to draw any but the most temporary conclusions from such sparse data. There is no doubt that if observations could be taken every hour a distinct diurnal variation in the difference between the velocity at two given heights would be obse ved, the velocity at the greater altitude probably tending towards a minimum about the same time that the velocity at the earth's surface reached its maximum. This would, however, only be found to be the case when the heights were about 1000 feet or more. Apart from actual determination by help of the instruments, however, the existence of such a diurnal variation has been several times forcibly brought to my notice by the fact that while during the middle of the day the kite frequently flies with great difficulty owing to the presence of vertical ascending and descending currents; towards evening, when the wind at the surface has often died away altogether, the kite flies at a higher altitude and pulls harder and steadier than it did during the day. This has so often occurred that I have ceased noting it as anything extraordinary. I may observe that such a condition is precisely what one would expect if the theory of the diurnal variation in the velocity of the surface wind given by Dr. Köppen in the *Zeitschrift der Oesterreichschen Gesellschaft für Meteorologie* for 1879, be accepted. According to this theory the expansion of the lower strata by solar action during the day, causes an intermixture of the air (*'uft austausch*) to take place between the upper and lower layers, by which the velocity of the lower layers is increased by the greater velocity which the descending air brings with it from above, while the upper layers have their velocity decreased by the smaller velocity with which the ascending lower air retarded by the asperities of the earth's surface, is endowed. Thus while the mean velocity of the atmosphere might remain about the same, the differences between the velocities above and below should undergo a diurnal period, the minimum difference occurring somewhat after midday. I was glad to see the other day that some observations on the velocity of the wind at some lofty observatory (I think Pike's Peak) showed that the diurnal period in the wind velocity at 8000 or 9000 feet, in exact opposition to what occurs at the earth's surface, exhibited a *minimum* about midday.[1]

Another feature that has been brought out by observing the flight of my kites, which frequently fly at heights of from 1300 to 1500 feet above the sea and thus enter the clouds, is the existence of a *courant ascendant* under cumulus and cumulo-stratus clouds. When such a cloud comes over, the kite rises up until the string is at an angle of 60° or more; but in proportion as it rises, so its pull becomes weak; the kite in fact lies on its face, and thus losing nearly all the horizontal component, the curvature of the string increases very much, and if an instrument is attached to it, it is sure to come down. After such a cloud has passed I have frequently noticed the apparent existence of a downward current which causes the kite to descend and at the same time increase its pull by the pressure being exerted more against a vertical surface.

Regarding the observations themselves, I am not aware that any similar ones have previously been made, except by Mr. Stevenson of Scotland. His plan was to fix anemometers to a pole 50 feet high or place them at different heights up a mountain. In the latter case it is not certain that the velocities represent what would occur in the free atmosphere at the same level. In the former, one is limited to poles of moderate height, and I do not at present see that anything else can compete with a kite-wire for greater heights; balloons, captive or otherwise, being of course out of the question where wind is concerned. Mr. Stevenson seems finally to have adopted a very simple formula for the increase of the velocity with the height, viz. that it is exactly prop rtional, or $\frac{V}{v} = \frac{H}{h}$. That though this might be true up to 50 feet it is certainly not true for greater heights I showed pretty conclusively in NATURE for March 29, 1883 (p. 506), where a discus ion of Dr. Vettin's cloud observations favoured the formula $\frac{V}{v} = \left(\frac{H}{h}\right)^{\frac{1}{4}}$ through a range of mo e than 20,000 feet.

Though I do not wish to try and determine any formula at this preliminary stage, it may be interesting to note the exponent

[1] This seems also to be the case on Ben Nevis, regarding which Mr. Buchan says, "In each of the months the maximum velocity is during the *night*, and the minimum during the *day*, being thus the reverse of what occurs at low levels and on plains" (*vide Journal* of the Scottish Meteorological Society, 3rd series, No. 1, p. 17).

yielded by the observations I have made, when grouped together roughly according to altitude. The results are :—

No. of obs.		Mean upper height		Mean lower height		Mean upper velocity		Mean lower velocity		Approximate value of exponent in formula
6	...	249	...	93	...	1630	...	1145	...	$\frac{1}{3}$
8	...	412	...	173	...	1751	...	1474	...	$\frac{1}{5}$
4	...	634	...	324	...	1987	...	1902	...	$\frac{1}{10}$

Thus, while the velocity invariably increases as we ascend, the rate rapidly diminishes after the first 200 or 300 feet. It must, however, be remembered that the place of observation is itself 500 feet above sea-level, and though this would probably not affect the results near the surface, the air above 200 feet must be moving with very nearly the same velocity as it would have at its real elevation above a sea-level surface. Adding therefore the 500 feet to both heights in the case of the two last groups, we get, for the value of x, $\frac{1}{2}$ and $\frac{1}{7}$ instead of $\frac{1}{5}$ and $\frac{1}{10}$. These two values are probably nearer the truth than those in the table, and hover round the mean value $\frac{1}{4}$, which I have already stated was found to hold for Vettin's cloud velocities up to 25,000 feet. In any case it is plain that Mr. Stevenson's formula cannot be taken to hold beyond his 50-foot pole.

Further observations will, I trust, give a trustworthy basis for determining the variations in the velocity-increment corresponding to the direction and absolute velocity of the wind as well as those corresponding to season, humidity, temperature, and pressure. To thoroughly investigate the velocity-increment under all such conditions, and thus to afford data to the physicist who desires to construct the hitherto unwritten science of aërodynamics, will be one of the objects of my experiments during the coming year.

P.S. *October* 22.—Since the foregoing observations were made I have succeeded in getting readings with the anemometers at heights of over 1100 feet above the ground, or 1600 feet above sea-level.

THE CLASSIFICATION AND AFFINITIES OF DINOSAURIAN REPTILES[1]

IN this paper the author presented briefly the results of a study of Dinosaurian reptiles on which he had been engaged for several years. The complete results will be published in a series of monographs now in preparation. The material on which the investigation is mainly based consists of the remains of several hundred individuals of this group collected in the Rocky Mountains by the author, and now preserved in the museum of Yale College. Other important American specimens have been examined by the author, who has also studied with care the more important specimens of this group in the museums of Europe. The investigation is not yet completed, but the results already attained seem to be of sufficient interest to present to the Association at this time.

In previous publications on this subject the author had expressed the opinion that the *Dinosauria* should be regarded, not as an order, but as a sub-class, and his later researches confirm this view. The great number of subordinate divisions in the group, and the remarkable diversity among those already discovered, indicate that many new forms will yet be found. Among those already known there is a much greater difference in size and structure than in any other sub-class of vertebrates, with the exception of the placental mammals. Compared with the Marsupials, living and extinct, the *Dinosauria* show an equal diversity of structure and size.

According to present evidence, the Dinosaurs were confined entirely to the Mesozoic Age. They were abundant in the Jurassic, and continued in diminishing numbers to the end of the Cretaceous period, when they became extinct. The great variety of forms that flourished in the Triassic renders it more than probable that some members of the group existed in the Permian period, and their remains may be brought to light at any time. The Triassic Dinosaurs, although very numerous, are known to-day mainly from footprints and fragmentary osseous remains; hence, many of the forms described cannot at present be referred to their appropriate divisions in the group. From the Jurassic, however, during which period Dinosaurian reptiles reached their zenith in size and numbers, representatives of no less than four well-marked orders are now so well known that different families and genera can be very accurately determined, and almost the entire osseous structure of typical examples, at least, can be made out with certainty. Comparatively little is yet known of Cretaceous Dinosaurs, although many have been described from incomplete specimens. All these appear to have been of large size, but much inferior in this respect to the gigantic forms of the previous period. The remains best preserved show that, before extinction, some members of the group became quite highly specialised.

Regarding the Dinosaurs as a sub-class of the REPTILIA, the forms best known at present may be classified as follows :—

SUB-CLASS DINOSAURIA.—Premaxillary bones separate; upper and lower temporal arches; rami of lower jaw united in front by cartilage only; no teeth on palate. Neural arches of vertebræ united to centra by suture; sacral vertebræ co-ossified. Cervical and thoracic ribs double-headed. Ilium prolonged in front of acetabulum; acetabulum formed in part by pubis; ischia meet distally on median line. Fore and hind limbs present, the latter ambulatory and larger than those in front; head of femur at right angles to condyles; tibia with procnemial crest; fibula complete. First row of tarsals composed of astragalus and calcaneum only, which together form the upper portion of ankle joint.

(I.) Order SAUROPODA (LIZARD-FOOT).—Herbivorous. Premaxillary bones with teeth. Large antorbital opening. Anterior nares at apex of skull. Post-occipital bones. Anterior vertebræ opisthocœlian; cervical ribs co-ossified with vertebræ; pre-sacral vertebræ hollow; each sacral vertebra supports its own transverse process. Fore and hind limbs nearly equal; limb bones solid. Feet plantigrade, ungulate; five digits in manus and pes; second row of carpal and tarsal bones unossified. Sternal bones parial. Pubes projecting in front, and united distally by cartilage; no post-pubis.

(1) Family *Atlantosauridæ*.—A pituitary canal. Ischia directed downward, with expanded extremities meeting on median line. Sacrum hollow. Anterior caudals with lateral cavities. Genera: Atlantosaurus, Apatosaurus, Brontosaurus.

(2) Family *Diplodocidæ*.—Dentition weak. Brain inclined backward. Large pituitary fossa. Two antorbital openings. Ischia with straight shaft, not expanded distally, directed downward and backward, with ends meeting on median line. Caudals deeply excavated below. Chevrons with both anterior and posterior branches. Genus: Diplodocus.

(3) Family *Morosauridæ*.—Small pituitary fossa. Ischia slender, with twisted shaft, directed backward, and sides meeting on median line. Anterior caudals solid. Sacral vertebræ solid. Genus: Morosaurus. European forms of this order: Bothriospondylus, Ceteosaurus, Eucamerotus, Ornithopsis, Pelorosaurus.

(II.) Order STEGOSAURIA (PLATED LIZARD).—Herbivorous. Feet plantigrade, ungulate; five digits in manus and pes; second row of carpals unossified. Pubes projecting free in front; post-pubis present. Fore limbs small; locomotion mainly on hind limbs. Cervical ribs free. Vertebræ and limb bones solid. Osseous dermal armour.

(1) Family *Stegosauridæ*.—Vertebræ bi-concave. Neural canal in sacrum expanded into large chamber; ischia directed backward, with sides meeting on median line. Astragalus co-ossified with tibia; metapodials very short. Genera: Stegosaurus (Hypsirhophus), Diracodon; and in Europe, Omosaurus (Owen).

2. Family *Scelidosauridæ*.—Astragalus not co-ossified with tibia; metatarsals elongated; four functional digits in pes. Known forms all European. Genera: Scelidosaurus, Acanthopholis, Cratæomus, Hylæosaurus, Polacanthus.

(III.) Order ORNITHOPODA (BIRD-FOOT).—Herbivorous. Feet digitigrade, five functional digits in manus and three in pes. Pubes projecting free in front; post-pubis present. Vertebræ solid. Cervical ribs free. Fore limbs small; limb bones hollow. Premaxillaries edentulous in front. A premandibular bone.

(1) Family *Camptonotidæ*.—Clavicles wanting; post-pubis complete. Genera: Camptonotus, Laosaurus, Nanosaurus; and in Europe, Hypsilophodon.

(2) Family *Iguanodontidæ*.—Post-pubis incomplete. Premaxillaries edentulous. Known forms all European. Genera: Iguanodon, Vectisaurus.

[1] Paper read at the Montreal Meeting of the British Association, by Prof. O. C. Marsh.

(3) Family *Hadrosauridæ.*—Teeth in several rows, forming with use a tesselated grinding surface. Anterior vertebræ opisthocœlian. Genera: Hadrosaurus (Diconius ?), Agathaumas, Cionodon.

(IV.) Order THEROPODA (BEAST-FOOT).—Carnivorous. Premaxillary bones with teeth. Anterior nares at end of skull. Large antorbital opening. Vertebræ more or less hollow. Feet digitigrade; digits with prehensile claws. Pubes projecting downward, with distal ends co-ossified.

(1) Family *Megalosauridæ.*—Anterior vertebræ convexo-concave; remaining vertebræ bi-concave. Pubes slender. Astragalus with ascending process. Genera: Megalosaurus (Poikilopleuron), Allosaurus, Cœlosaurus, Creosaurus, Dryptosaurus (Lælops).

(2) Family *Labrosauridæ.*—Lower jaws edentulous in front. Cervical and dorsal vertebræ convexo-concave. Pubes slender, with anterior margins united. Astragalus with ascending process. Genus: Labrosaurus.

(3) Family *Zanclodontidæ.* — Vertebræ bi-concave. Pubes broad elongate plates, with anterior margins united. Astragalus without ascending process. Five digits in manus and pes. Genera: Zanclodon (?), Teratosaurus.

(4) Family *Amphisauridæ.*—Vertebræ bi-concave. Pubes rod-like. Five digits in manus, and three in pes. Genera: Amphisaurus (Megadactylus ?), Bathygnathus (?), Clepsysaurus, Palæosaurus, Thecodontosaurus.

(*a*) Sub-order CŒLURIA.—(5) Family *Cœluridæ.*—Vertebræ and bones of skeleton pneumatic. Anterior cervicals convexo-concave; remaining vertebræ bi-concave. Cervical ribs co-ossified with vertebræ. Metatarsals very long and slender. Genus: Cœlurus.

(*b*) Sub-order COMPSOGNATHA.—(6) Family *Compsognathidæ.*—Cervical vertebræ convexo-concave; remaining vertebræ bi-concave. Three functional digits in manus and pes. Ischia with long symphisis on median line. Genus: Compsognathus.

(*c*) Sub-order CERASTOSAURIA.—(7) Family *Ceratosauridæ.*—Horn on skull. Cervical vertebræ plano-concave; remaining vertebræ bi-concave. Pubes slender. Pelvic bones co-ossified. Osseous dermal plates. Astragalus with ascending process. Metatarsals co-ossified. Genus: Ceratosaurus.

The four orders defined above, which the author first established for the reception of the American Jurassic Dinosaurs, appear to be all natural groups, well marked in general from each other. The European Dinosaurs from deposits of corresponding age fall readily into the same divisions, and, in some cases, admirably supplement the series indicated by the American forms. The more important remains from other formations in this country and in Europe, so far as their characters have been made out, may likewise be referred with certainty to the same orders.

The three orders of herbivorous Dinosaurs, although widely different in their typical forms, show indications of approximation in some of their aberrant genera. The *Sauropoda* for example, with *Atlantosaurus* and *Brontosaurus*, of gigantic size, for their most characteristic members, have in *Morosaurus* a branch leading towards the *Stegosauria*. The latter order, likewise, although its type genus represents in many respects the most strongly marked division of the Dinosaurs, has in *Scelidosaurus* a form with some features pointing strongly toward the *Ornithopoda*.

The carnivorous *Dinosauria* now best known may all be placed at present in a single order, and this is widely separated from those that include the herbivorous forms. The three sub-orders here defined include very aberrant forms, which show many points of resemblance to Mesozoic birds. Among the more fragmentary remains belonging to this order, this resemblance appears to be carried much farther.

The *Amphisauridæ* and the *Zanclodontidæ*, the most generalised families of the *Dinosauria*, are known only from the Trias. The typical genera, however, of all the orders and sub-orders, are Jurassic forms, and on these especially the present classification is based. The *Hadrosauridæ* are the only family confined to the Cretaceous. Above this formation there appears to be at present no satisfactory evidence of any *Dinosauria*.

The peculiar orders *Hallopoda* and *Aetosauria* include carnivorous reptiles which are allied to the *Dinosauria*, but they differ from that group in some of its most characteristic features. In both *Aetosaurus* and *Hallopus* the calcaneum is much produced backwards. In the former genus the entire limbs are crocodilian, and this is also true of the dermal covering. In both of these genera there are but two sacral vertebræ, but this may be the case in true Dinosaurs, especially from the Trias. Future discoveries will probably bring to light intermediate forms between these orders and the typical Dinosaurs. The *Crocodilia* have some some strong affinities with the *Dinosauria*, especially with those of the order *Sauropoda*. The extinct genus *Belodon* of the Triassic, for example, resembles *Diplodocus*, particularly in the large antorbital vacuities of the skull, the posterior position of the external nasal aperture, as well as in other features. The *Rhynchocephala*, represented by the genus *Hatteria*, have several important characters in common with the *Dinosauria*, and, as the former is evidently an ancient type, it is probable that a real affinity may exist between these two groups.

That birds are closely related to Dinosaurs there is no longer any question. In addition to the various characters which these groups have been known to share with each other, two more may be added in consequence of discoveries made during the past year. The genus *Ceratosaurus*, a carnivorous Dinosaur from the Jurassic of the Rocky Mountains, recently described by the author, has the pelvic bones co-ossified, as in all known birds, living and extinct, except *Archæopteryx*. The same reptile, moreover, has the metatarsal bones firmly united, as in all adult birds, with possibly the single exception of *Archæopteryx*, while all the known *Dinosauria*, except *Ceratosaurus*, have both the pelvic and the metatarsal bones separate. The exception in each case brings birds and reptiles near together at this point, and their close affinity is now a matter of demonstration.

THE DANISH EXPEDITION IN GREENLAND

WE have on previous occasions referred to the Expedition under Lieuts. Holm and Garde, which has for more than a year been engaged in exploring the east coast of Greenland, and we are now able to supplement this with an interesting report from Lieut. Holm, written in the spring, from the winter quarters of the Expedition, and received some time ago by sailing-vessel at Copenhagen.

The place where the Expedition wintered is called Namortalik, and lies on the east coast, about fifty miles, as the crow flies, from Cape Farewell. It is also called Björneorten (the "bear-haunt"), from the many bears in the neighbourhood. After an excursion lasting two months and a half during the summer of 1883, the Expedition returned in September to Namortalik, but the huts for wintering not being finished, they started for a week's further excursion to the Fredriksdalsfjord, between Namortalik and Cape Farewell.

It was not until the end of October that the Expedition could begin their regular scientific observations at the station, but after that date they were continued without interruption through the winter. As, however, the chief object of the Expedition was to explore the east coast in boats, the scientific observations have not been so rich as those, for instance, of the Danish International Expedition at Godthaab in 1882-83 (NATURE, vol. xxix. p. 337); but every effort was made to adhere as strictly as possible to the programme of the International Polar Commission. The meteorological observations were made every third hour from 8 p.m. to 8 a.m., and the magnetic observations every hour except at 3 and 4 a.m. On the 1st and 5th of every month the magnetic instruments were read every fifth minute during eight hours and every twentieth second during one hour.

With reference to the climatological conditions of the east coast, we learn that the winter is very raw and severe, although it cannot be said to be of excessive duration. The pleasant, calm, frosty weather which is experienced in North Greenland seldom prevails on the east coast, but in its stead there are frequent and sudden changes and violent storms; there being, for instance, one day 20° C. of frost, and the next several degrees of heat, while heavy rains and snows alternate. In consequence of these sudden changes it is impossible in East Greenland to employ the mode of locomotion so valuable in other parts, viz. the dog-sledge. The only means of conveyance here is by boat. If, therefore, the sea is frozen over for a time, the inhabitants remain where they are, and wait patiently until a higher temperature removes the obstacle. The ice never becomes firm enough to bear a man and sledge.

Up to January last the temperature had not fallen lower than 15°·5 C.—about Christmas—the glass generally standing between

4° and 6°, and even on some days not lower than zero (= 32° F.). This was particularly the case whilst the north-east "Föhn" wind prevailed, to which East Greenland is indebted for its comparatively mild winters; but there are places where the ice lies firm throughout the winter. On December 5, during a "Föhn" wind, the thermometer rose to + 10° C. After the beginning of the new year, however, the cold became more severe, and the "Föhn" winds less frequent.

Towards the end of January and in February the thermometer sometimes registered 20° C. of frost, and on March 9 it fell to − 21°·5, the lowest temperature registered during the winter.

Some interesting particulars are also given of the almost unknown district in which the Expedition wintered. The station Namortalik is described as situated on an island, and as having a population of 250 souls. The island, which bears the same name, is surrounded by several others, which, lying further out to sea, are visited during the spring by the natives, who catch seals and eider-ducks there. To the north the scenery of Greenland is seen in all its grandeur and beauty; wild mountains with lofty cones rising above the clouds. These are on the beautiful but almost unapproachable island of Sermerok. If the air be clear, and the weather calm and sunny, the little island lies so peacefully in the ocean that one feels tempted to climb the lofty mountains; but when the storm hovers around the peaks, half hidden in drifting clouds, and the Polar Sea is a mass of foam, the giant forms of the mountains deter even the boldest. The mainland is rugged, like the island just mentioned; in fact, the whole southern portion of Greenland is a region of wild mountains, furrowed by tremendous ravines, and rising to a height of nearly 8000 feet, from which enormous glaciers descend to the sea. The landscape produces by its wildness and desolation very striking impressions.

There are thirty little turf-covered houses at Namortalik, including a bakery and a brewery. The so-called "Royal Commerce of Greenland," a Danish Company, has also a depot here. There is, besides, a Lutheran mission, a church, and a school attended by half-caste Greenlanders.

The Expedition has erected two observatories on the rocks, about 1000 feet from the dwelling-houses, but connected by telephone.

Close to Namortalik is the Tasermint Fjord, some fifty miles in length, one of the loveliest in South Greenland. On its shores the vegetation is very luxuriant in summer, and the heat and mosquitoes are so troublesome that one could imagine one's self in the tropics. This fjord is of great importance to the Namortalik people, as its shores provide them with fuel, its streams and waters with salmon, seals, and herrings, and its mountain-slopes with ptarmigans, Polar hares, and foxes.

When the summer commenced, the Expedition intended to leave their quarters, and continue the exploration of the east coast; but there is at present no news of their achievements this summer. The programme is, however, to explore the east coast by sea and land as far north as possible, and to get into communication with the natives whenever opportunity offers, in which latter attempt nearly all previous Expeditions have been disappointed.

At the beginning of this winter one half of the Expedition was to return to Namortalik, while the second endeavoured to spend the winter as far north as possible. The Expedition will leave Greenland in the autumn of next year.

SCIENTIFIC SERIALS

Journal of Botany, August to November.—The most important article in the recent numbers of this magazine is Mr. Charles Bailey's paper on the structure, &c., of *Naias graminea*, Delile, var. *Delilei*, Magnus, illustrated with four plates and many woodcuts. This interesting addition to the British flora—first found in 1883 in a canal in Lancashire—is a native of warmer climates, not being indigenous anywhere in Europe, and has probably been introduced with Egyptian cotton. Mr. Bailey gives an exhaustive account of the morphology of its various organs, and especially of its mode of fertilisation. The *Naias* belongs to a class of plants that may be called "protozoophilous," the pollen being carried to the stigma by aquatic animals of low organisation, in this instance by the currents caused by the rotating cilia of species of Vorticellidæ.—Most of the other articles in these numbers are of more limited interest, being topographical papers on the flowering plants or cryptogams of particular districts, or descriptions of new or little-known species.—Additional instalments are also given of Mr. J. G. Baker's synopsis of the genus *Selaginella*, which is still uncompleted, the species now described amounting to 180.

Nuovo Giornale Botanico Italiano, July to October.—The greater part of the space in the July number of this magazine is occupied by descriptive papers. The paper of most general interest is that by A. Piccone, on the algæ of the Red Sea. He shows that the algal flora of this sea shows much closer affinities to that of the Indian Ocean than of the Mediterranean. It is characterised by the small number of diatoms and of green algæ generally, by the entire absence of Laminarieæ, and, above all, by its extraordinary richness in species of *Sargassum*, many of them endemic.—In the October number are a synopsis of the flora of Sicily, and a list of the "pronubi" or insect-fertilisers of flowering plants in Calabria and Piedmont; also a note by R. Pirotta, showing, from an examination of the oospores, the identity of *Cystopus capparidis*, parasitic on the caper, with *Cystopus candidus*, the common parasite of cruciferous plants.

SOCIETIES AND ACADEMIES

London

Linnean Society, November 6.—Sir J. Lubbock, Bart., President, in the chair.—A letter was read intimating that their late President, Mr. G. Bentham, had bequeathed in his will a legacy of 1000*l*. to the Society.—A notice of invitation for the Fellows to attend the centenary (December 4) of the Royal Bohemian Society of Natural History in Prague was also read from the chair.—Mr. W. T. Thiselton Dyer exhibited the following plants and their products:—(1) *Vaccinium arctostaphylus*, from which the Trebizonde tea ("Thé-du-Bu-Dagh") is prepared at Amassia and Tokat. The tea has a pleasant odour, but a somewhat harsh taste when drunk. (2) *Pueraria Thunbergiana*, specimens of this Corean plant and of the cloth made from it. (3) *Pachyrhyza sinensis*, with the native name of "Ko-poo," a leguminous plant from the fibres of which the yellow and more expensive summer cloth is made.—Mr. Thos. Christy showed and made remarks on a specimen of *Kola acuminata*.—Mr. R. A. Rolfe afterwards exhibited examples of British oak-galls produced by Cynipidean insects of the genus *Neuroterus*. These were the silk-button gall formed by *N. numismatis*, the globose gall produced by *N. ostreus*, the smooth-spangle gall formed by *N. fumipennis*, the scarce-spangle gall formed by *N. læviusculus*, and the common spangle gall produced by *N. lenticularis*, as also a purple variety of the latter gall. He stated that the plan and details of the galls depend on the nature of the irritating fluid deposited by the insect; but on the other hand the different species of oak seem to have an influence in determining certain variations as to colour, and, it may be, general growth, of the galls.—Mr. Geo. Brook read a paper on the development of the Five-bearded Rockling (*Motella mustela*) in which the following points were enunciated:—(1) Whereas there is only one large oil globule in the normal egg of *Motella*, sometimes this is subdivided into from two to eight or even more; but in these cases there is always an abnormal development which often results in the death of the embryo. In those that survive, the small oil globules always coalesce to form one large one before the embryo hatches. (2) In the further development of the newly-hatched embryo there is a cranial flexure produced which is analogous to that so characteristic of Elasmobranchs. This is caused by the rapid development of the dorsal portion of the head, while the ventral portion remains comparatively quiescent. Later, the ventral portion plays its part, and, with the development of the jaws the brain is pushed back to its normal position. (3) As in other pelagic Teleostean eggs, there is no circulation observable either in the embryo or in the vitellus up to the time of hatching, nor indeed for some days afterwards. (4) In *Motella* the anal gut does not open on the ventral surface for at least a week after hatching. Ryder has shown the same to be the case with the cod-fish, so that the young *Gadidæ* would not appear to be in a position to take solid food at nearly so early a period in their existence as is usual with Teleosteans. Mr. Brook also called attention to the influence of temperature on the rate of development of pelagic eggs, and suggested that, until we know the temperature at which the various observations are made on these forms, no true comparison can be established.—The next communication was on a collection of

plants made in Timor Laut by Henry O. Forbes. Therein a short account is given of the nature of the islands and of the general character of the vegetation, after which comes a technical list of about eighty plants.—Prof. Oliver adds a note that, "This collection, so far as it goes, is made up in great part of the more widely diffused species of the Indian Archipelago. The most interesting plants appear to be: one in fruit only, referred to the meliaceous genus *Owenia*, probably *O. cerasifera*, Muell., of Queensland; a fine *Mucuna*, of the section Stigolobium; a *Selarbrea*, an araliaceous genus hitherto only received from New Caledonia, and a fruit of possibly a *Strombosia*. Mr. Forbes himself is inclined to regard the Timor Laut flora and fauna as having affinities with the Moluccan (Amboina) region.—A paper by T. H. Potts was read, containing notes on some New Zealand birds. This consisted chiefly of field observations on the habits of the quail hawk, harrier, owl, kaka, kea, long-tailed cuckoo, kingfisher, and native wren.—There followed a note on the reproduction of the heterœcismal Uredines by Charles B. Plowright. Therein the author affirms that, when the reproduction of these fungi takes place without the intervention of Ascidiospores, the resulting Uredospores are far more abundant than in the case when they arise from the implantation upon the host plant of the Ascidiospores, this inference being supported by various detailed observations of the author.

Zoological Society, November 4.—Prof. W. H. Flower, F.R.S., President, in the chair.—Mr. Sclater exhibited and made remarks on the skin of a Woolly Cheetah (*Felis lanea*), obtained at Beaufort West, South Africa, sent to him by the Rev. G. H. R. Fisk, C.M.Z.S.—The Secretary exhibited, on behalf of Major W. Brydon, B.S.C., C.M.Z.S., an egg of Blyth's Tragopon; and on behalf of Mr. J. C. Parr, F.Z.S., a specimen of the chick of the Vulturine Guinea-fowl (*Numida vulturina*) hatched in Lancashire.—The Rev. H. H. Sclater, F.Z.S., exhibited a specimen of the Barred Warbler (*Sylvia nisoria*) obtained on the Yorkshire coast.—Mr. H. E. Dresser, F.Z.S., exhibited specimens of the Barred Warbler (*Sylvia nisoria*) and of the Icterine Warbler (*Hypolais icterina*), killed in Norfolk.—Mr W. B. Tegetmeier, F.Z.S., exhibited a specimen of the File-fish (*Balistes capriscus*), which had been recently caught off Folkestone.—Mr. F. E. Beddard, F.Z.S., read a paper on the anatomy of a gigantic Earthworm, *Microchæta rappii*, and pointed out its systematic position. For this very interesting specimen the author was indebted to the Rev. G. H. R. Fisk, C.M.Z.S., of Cape Town.—Mr. A. G. Butler, F.Z.S., gave an account of a collection of Lepidoptera made by Major J. W. Yerbury at or near Aden. The author looked upon this collection as one of the greatest interest, since it not only contained a fine series of the beautiful species of *Teracolus* recently described by Col. Swinhoe, but also many remarkable intergrades between certain long-established species, tending to prove either that hybrids between allied species are fertile, or that in Aden a condition of things still exists which in Asia proper and in Africa has long passed away.—A communication was read from Lieut.-Col. C. Swinhoe, F.Z.S., containing an account of the Lepidoptera collected by him at Kurrachee between the years 1878 and 1880.—A communication was read from Mr. Thomas H. Potts, of Ohinitaki, New Zealand, in which he described a case of hybridism between two species of Fly-catchers of the genus *Rhipidura*.

Mathematical Society, November 13.—Prof. Henrici, F.R.S., President, in the chair.—Prof. Karl Pearson was elected a member of the Society.—The Chairman in very feeling terms referred to the losses the Society and he himself personally had sustained by the deaths of Prof. Rowe, a member of the Council, and of Prof. Townsend, F.R.S., during the recess. After a slight pause, he presented the De Morgan Medal to Prof. Cayley.—The Treasurer's report, showing that the financial position of the Society was most satisfactory, and the Secretary's report having been read, the meeting balloted for and duly elected the following gentlemen to constitute the Council for the present session:—President: J. W. L. Glaisher, F.R.S.; Vice-Presidents: Dr. Henrici, F.R.S., Prof. Sylvester, F.R.S., J. J. Walker, F.R.S.; Treasurer: A. B. Kempe, F.R.S.; Secretaries: M. Jenkins, R. Tucker; other members: Prof. Cayley, F.R.S., Sir J. Cockle, F.R.S., E. B. Elliott, Prof. Greenhill, J. Hammond, H. Hart, Dr. Hirst, F.R.S., S. Roberts, F.R.S., and R. F. Scott.—Mr. Tucker then read abstracts of the following papers:—On the theory of screws in elliptic space (supplementary note), and on the theory of matrices, by A. Buchheim; on sphero-cyclides, by H. M. Jeffery, F.R.S.; results from a theory of transformation of elliptic functions, by J. Griffiths; on the limits of multiple integrals, by H. MacColl; on the motion of a viscous fluid contained in a spherical vessel, by Prof. H. Lamb, F.R.S.; on certain conics connected with a plane unicursal quartic, by R. A. Roberts; note on elliptic functions, on an integral transformation and a theorem in plane conics, by Asutosh Mukhopâdhyây. He then stated that he had found that the six Simson-lines corresponding to the angular points of the pedal and medial triangles of a given triangle with reference to the medial and pedal triangles respectively, the circum-circle being in this case the nine-point circle, co-intersect in a point which lies on the axis connecting the circum-centre and the Symmedian-point, midway between the circum-centre and the ortho-centre of the pedal triangle, and is also the centre of Mr. H. M. Taylor's circle.—The President (Prof. Henrici taking the chair) brought the meeting to a close by reading a paper on certain systems of q-series in elliptic functions, in which the exponents in the numerators and denominators are connected by recurring relations.

Geological Society, November 5.—Prof. T. G. Bonney, F.R.S., President, in the chair.—The Secretary announced the gift to the Society of a water-colour picture of the hot springs of Gardiner's River, Wyoming Territory, U.S.—The following communications were read:—On a new deposit of Pliocene age at St. Erth, fifteen miles east of the Land's End, Cornwall, by S. V. Wood, F.G.S. The deposit in question, about five miles north-east of Penzance, consisted of a tenacious blue clay with shells, resting on sand, and passing upwards into a yellow unfossiliferous clay, overlain unconformably by the earth with angular fragments, under which were buried the ancient beaches of the British Channel. Of over forty species of Mollusca obtained by the author some appeared to be wholly new, others characteristic species of the Red Crag, some not known alive, some still living. Most interesting of all, six species of Nassa were, all but one (*N. granulata*, Sow., or *granifera*, Dujardin), unknown from any formation of Northern Europe, and occurring, living or fossil, only in the southern half of Europe. Of these *Nassa mutabilis*, Linné, lived in the Mediterranean, but otherwise not north of Cadiz, while two others were new species of this southern *mutabilis* group. In the opinion of the author the bed was Pliocene, and newer rather than older, coeval with the Red Crag, but having more affinities with the Pliocene of Italy than with that of the North Sea region, a fact which seemed to indicate that during its deposition the only communication between the Atlantic and the North Sea was round the coast of Britain, a passage unavailable to the Italian group of Nassa on account of the refrigeration of its 9° of latitude. The bed was the deposit of a strait connecting the present St. Ives Bay with Mount's Bay, and detaching the high ground of the Land's End district from the rest of Britain. The shell-bearing part of the clay was 98 feet above mean-tide mark in Hayle Estuary. Dr. Gwyn Jeffreys, in a discussion on the paper, recognised among the fossils of the St. Erth deposit forty-four or forty-five species, eleven or twelve recent, thirty-three or thirty-four extinct. A bed near Antibes, in the south of France, seemed to resemble the St. Erth deposit, and the Mollusca of the two should be critically compared.—On the Cretaceous beds at Black Ven, near Lyme Regis, with some supplementary remarks on the Blackdown beds, by the Rev. W. Downes, F.G.S. The cliff section measured 300 feet in height, the Lias occupying 200 feet and the Cretaceous beds 100 feet, of which the lower 25 feet were a black loamy clay, and the upper 75 feet yellowish-brown noncalcareous sands. From one point in the clay the author obtained a few fossils, the most abundant being *Lima parallela*, and 50 feet above that point was a small patch of fragmentary silicified fossils. In the author's opinion the fauna of the sands approached the Blackdown fauna, and from all the evidence he had found, concluded that the conditions of deposition rendered it impossible to recognise in the Cretaceous beds of the West of England the subdivisions of Gault and Upper Greensand so well marked to the eastward.—On some recent discoveries in the submerged Forest of Torbay, by D. Pigeon, F.G.S. The submerged forest rested on clay, the soil in which the forest grew, which, again, rested on Trias, a breccia of Devonian fragments intervening in places. During the gales of 1883-84, two aggregations of rolled trap pebbles were found, these pebbles having probably served as smelting-hearths. In their neighbour-

hood were discovered an ingot of copper, some tin slag, a piece of glass, flint implements, &c., together with remains of piles driven into the ground—traces of human work belonging, apparently, to the Bronze Age. The author thought it the more probable view that the clay bed was deposited in a shallow marsh of land-water kept back by the sea-beach, then some hundreds of feet further to seaward, and that the forest, which consisted chiefly of willows, grew on the marsh.

EDINBURGH

Mathematical Society, November 14.—Dr. Thomas Muir, F.R.S.E., President, in the chair.—Mr. John S. Mackay read a paper on the geometrical figure known to the Greeks as "The Shoemaker's Knife."—The following office-bearers were elected:—President: Mr. A. J. G. Barclay; Vice-President: Mr. George Thom; Secretary: Mr. A. Y. Fraser; Committee: Drs. R. M. Ferguson and Thomas Muir, Messrs. R. E. Allardice, W. J. Macdonald, John S. Mackay, and David Munn.

PARIS

Academy of Sciences, November 10.—M. Rolland, President, in the chair.—Additions to the memoir on complex unities, by M. L. Kronecker.—Remarks on the fourth part of the map of Africa, presented to the Academy, on behalf of the Minister for War, by Col. Perrier. This map has been prepared by Capt. de Lannoy, of the War Department, on a scale of 1 : 2,000,000. The present part comprises the whole of the Congo region, in six sheets, which have been issued for the use of the members of the International Congress now assembled in Berlin to discuss matters relative to West Africa.—Note on Messrs. Renard and Krebs' new balloon, by M. Hervé Mangon. Two ascents were again made on Saturday, November 8, which are described as completely successful. On the first occasion the machine was propelled at an absolute speed of 23 kilometres per hour against the wind blowing at the rate of 8 kilometres per hour. The problem of directing balloons independently of aërial currents is regarded by the author as practically solved by these experiments.—Observations, elements, and ephemerides of Wolf's comet, by M. Gonnessiat. The observations were made with the Brunner 6-inch equatorial of the Lyons Observatory.—Observation of the same comet made with the meridian circle of the Bordeaux Observatory, by M. Courty.—Note on the sinuosities and variations of curvature in the shadows cast during lunar eclipses, by M. P. Lamey.—On an equation analogous to Kummer's equation, by M. E. Goursat.—On algebraic curves of any degree described on a plane, by M. Maurice d'Ocagne.—On atomic and molecular movements, by M. M. Langlois.—On the depth to which sunlight penetrates the waters of the Lake of Geneva, by MM. H. Fol and Ed. Tarasin. From a series of experiments carried out in August and September of this year the authors conclude that light reaches a depth of 170 metres and probably a little more, the luminosity at this point being about equal to that of a clear moonless night.—On a general statement of the laws of chemical equilibrium, by M. H. Le Chatelier.—Note on the polymorphism of the phosphate of silica, by MM. P. Hautefeuille and J. Margottet. The authors infer from several experiments that at temperatures ranging from 300° to 1000° C. this phosphate crystallises spontaneously in four crystallographic forms incompatible with each other, and consequently constituting four distinct chemical species.—On fluoretted apatites, by M. A. Ditte.—On the action of the primary alcoholic iodides on the fulminate of silver, by M. G. Calmels.—Anaytical study of the atmosphere of the city of Algiers, by M. Chairy.—On the hydrate of neutral sulphate of alumina, by M. P. Marguerite-Delacharlonny.—Saponification of the simple aromatic ethers of neutral substances, by M. A. Colson.—The microbe of yellow fever: prophylactic inoculation, by MM. D. Freire and Rebourgeon. After a series of extensive experiments conducted at Rio de Janeiro during the years 1880-84, Dr. Domingos Freire has succeeded in attenuating the virus of yellow fever and reducing it to a vaccinal virus. With this, 400 persons have already been treated with complete success. But fresh experiments will be needed to determine the duration of immunity obtained by this perventive inoculation.—On the effects of inflation of the lungs with compressed air, by MM. Gréhant and Quinquaud.—Researches on the genesis of saccharine in beetroot, by M. Aimé Girard.—On peptonic fermentation, by M. V. Marcano. This new process is described as a simple and economic means of preparing in a few hours extremely pure peptone at a cheap rate. It is capable of being advantageously applied in a large way to the exportation of meat in a far more nutritive and economic form than that of the extracts of meat now in use.—Origin and mode of formation of the phosphates of lime found deposited in large quantities in sedimentary lands: their connection with the iron ores and clays of siderolithic levels, by M. Dieulefait.—Contributions to the anatomy and morphology of the Malpighian vessels in the Lepidoptera, by M. N. Cholodkovsky. Completion of the biological evolution of *Chaitophorus aceris*, Fabricius (sub-Aphis), by M. J. Lichtenstein.—Note on the characteristics of a Tertiary Conifer (*Araucarites Sternbergi*, Goepp.) allied to the Dammareæ (*Doliostrobus Sternbergi*), by M. A. F. Marion.—On a great oscillation of the Cretaceous seas in Provence, by M. L. Collot.—On the limestones containing fossil Echinids occurring at Stramberg, Moravia, by M. G. Cotteau.—Observations of the solar corona in Algeria, by M. E. Fuchs.—Account of a magnificent meteor observed at Morges on November 3, by M. Ch. Dufour.

VIENNA

Imperial Academy of Sciences, October 16.—On bodies with a maximum of density, and on the conclusions derived from their behaviour, by C. Puschl.—On the passing of luminous rays through glass pipes, and on a method based thereupon for determining the refractive indices of condensed gases, by T. Dechant.—On the influence of pressure on the magnetisation of iron and steel rods, by H. T. Ibrailean.—Computation of the orbit of the planet Cœlestina (237), discovered by T. Palisa on June 27, by F. von Oppolzer.—Geographical determination of the place of San'a (capital of the Yemen Vilayet), by E. Glaser.—Calculation of the orbit of Wolf's comet, by K. Zelbr.—On the action of zinc-ethyl on $\alpha\beta$ dichlorocrotonaldehyde, by A. Lieben.

OVER-PRESSURE IN ELEMENTARY SCHOOLS

THERE has lately arisen a warm controversy about over-pressure in schools, and its alleged results. The points in dispute are unquestionably important, and deserve the careful thought of all those who are interested in the intellectual and physical development of the rising generation. The cry of over-pressure was raised some years ago with reference to middle-class schools, and during the discussion of the Proposals of the Education Department for the New Code it extended to elementary schools. The National Union of Elementary Teachers took up the subject at their meeting at Sheffield during the Easter week of 1882. In July they had an important conference with Members of Parliament at the House of Commons, and they have continued ever since to agitate for a relaxation of Government requirements. Their views were supported by the opinions of several medical men, and were gladly seized hold of by the opponents of the education of the people. The matter came before the Social Science Congress at Huddersfield and the Health Exhibition at South Kensington. It has been investigated and reported on by several School Boards. The *Times* has dealt with it in able leading articles, and the *Pall Mall* in prettily written "Idylls." The Education Department itself, and both Houses of Parliament, have been stirred by it, while the personal combat between Dr. Crichton Browne, one of the Lord Chancellor's Visitors, on the one side, and Mr. Fitch, one of the best known and most highly esteemed of Her Majesty's Inspectors, on the other, has added a flavour to the controversy.

The question is a large and complicated one. In dealing with it I have no intention of touching on any personal matters in dispute, nor of speaking of the pressure on School Board members, or on teachers. Our educational systems exist for the sake of the children, and must stand or fall according to the effect upon them. My remarks also will be restricted to public elementary schools, whether "voluntary" or "Board," though I do not believe that they are so open to the charge of over-pressure as many of our middle-class or higher schools.

The allegations are of the most serious order. It is not so much that here and there one poor child dies of disease brought on by over-work; but it is held that the bodies of our scholars are being systematically sacrificed to an abnormal development of their minds, and that there is growing up a generation whose nerves are over-strung, and who are becoming more and more liable to diseases of the brain and connected organs. The defenders of the present system, however, assert that these charges are enormously exaggerated, and that all reasonable precautions are taken against the occurrence of the evil.

In all this conflict it is difficult to find evidence of a scientific character; there is more rhetoric than argument, and even when the figures of speech are supplemented by statistics, the conclusions drawn from them seem open to question. There are, however, two conclusions which will scarcely be disputed by any one who has looked at the matter with any amount of impartiality.

(1) *That in all large schools there are children who are in danger of over-pressure.* Take the typical case of a class of seventy children, starting with about the same attainments. The bulk of these will be average boys, or girls, as the case may be, fairly healthy and intelligent, not given to over-much study, but still ready to fall in with the requirements of the school. But there will also be some half-starved children, who often come without any breakfast, dull children—descendants of a wholly uncultured race—feeble children, and others averse to any restraint and constitutionally irritable, together with children who are weary with toil at home, or with hanging about late at night, or working early in the morning before they go to school. Besides these there are the exceptionally clever children, who are in danger of under-pressure, and the over-sensitive or ambitious, who are prone to over-work themselves if allowed the opportunity. It is evident that the general scope of the instruction must be adapted to the average of the class. To reduce it to the level of the physically or mentally weak would be a cruel wrong to the majority of the children, and an injustice to the public, who, by means of taxes, rates, or voluntary contributions, mainly support the school.[1] But this insures the possibility of more being expected from some of the other boys or girls than they have the power to perform. This danger is aggravated where, as in many country parishes, it is difficult to raise sufficient funds to provide a proper staff and appliances for teaching, while the very existence of the school is dependent upon each child earning as large a Government grant as possible. The danger is aggravated also by the shocking irregularity with which those children attend who are driven in from the streets. Happily elementary schools are usually exempt from one prolific source of over-pressure—competitive examinations. The annual Government examination is simply for a pass, and is looked forward to with pleasure by the majority of the children.[2] The practice of the more important bodies of management is, I believe, similar in this respect to that of the London School Board, which recognises no competition between one child and another, unless it be for the Scripture prizes and a few scholarships, which it administers for other parties.

(2) *That in a large number of instances the circumstances of school life are more favourable to health than the home life.* Before the days of compulsory education many thousands of children passed a joyless existence shut up in close and often fetid rooms, or turned out in all weathers into the streets or alleys. Now these children are brought into warm, well-lighted, and well-ventilated school-rooms, where habits of cleanliness and self-respect are inculcated, and where both their bodies and minds are duly exercised. This is especially the case in the newly-constructed Board schools. It is difficult to show this improvement by statistics of health, but we have the statistics of death. The Registrar-General, having been applied to on this matter, reported that "the death-rate of children (from five to fifteen years of age) in 1861-70 was 6·3 per 1000. It fell in 1871-80 to 5·1 per

[1] So far from the majority of the children being over-pressed, it is admitted by Dr. Crichton Browne that 70 or 80 per cent. can accomplish the annual work required by the Code easily.

[2] An attendance-officer, formerly a schoolmaster, has just written to me as follows:—"I have ever found the children looking anxiously and joyously forward to the day of examination, so much so that it would be nothing short of absolute cruelty to deprive any of those dear little souls of their long-hoped-for privilege."

1000, a decline of 19·05 per cent."; that "the main part in this fall was due to diminished mortality from the chief zymotic diseases"; that death from other diseases had also declined, "whereas the death-rate from nervous affections remained unaffected," or, possibly, slightly increased. A diminution of 19 per cent. in the death-rate is a great gain, and that this is not to be wholly or mainly attributed to improved sanitary conditions in their dwellings is shown by the fact that the diminution of mortality is much smaller in children under the school age.[1] But the question arises, granted that going to school is in the main favourable to health, what about these nervous diseases? Is their probable increase the result of increased attendance at school during the last decade? Dr. Crichton Browne has drawn out and discussed at great length the statistics of lunacy and the mortality from hydrocephalus, cephalitis, diabetes, nephritis, Bright's disease, uræmia, rheumatic fever, and rheumatism, and shows that during the five years 1876–80 there was an increase of these diseases. But the remarkable fact comes out that this increase has affected all ages. The increase of death from diseases of the kidneys has been greater among persons of twenty years and upwards, and the increase from inflammation of the brain and its membranes has been greater among children under five years of age than among those who have attended school during the period in question.

But the statistics of disease would be more valuable than those of death. Unfortunately they scarcely exist. Dr. Crichton Browne has, however, tabulated the results of his inquiries on this subject in eleven London schools. In regard to headache, to which he has naturally paid great attention, he has arrived at the startling conclusion that "as many as 46·1 per cent. of the children attending elementary schools suffer from habitual headache." He analyses the nature of these headaches very fully, but to ask a class of children to hold up their hands in response to the question, "How many boys or girls here suffer from headaches often, or now and then?" is far from being a scientific method of procedure. His tables of comparison between the different Standards seem to me more valuable as evidence. If any real mischief is going on in our schools, it will betray itself in the evil being more apparent among those children who have been longest at school. In the case of short-sightedness, which, from investigations on the Continent, Mr. Brudenell Carter's inquiries at home, and other sources of information, we know to be a growing malady, the increasing percentage from Standard I. to Standard VI. is very apparent from Dr. Browne's table, rising, as it does, from 2·5 to 9·2. In the case of headache there is a slight increase; but in the case of sleeplessness and neuralgia or toothache there is a very marked decrease. No doubt the inquiry is a very complex one, and it is impossible to separate the different factors in the result, but these tables certainly invalidate rather than support the opinion that the nervous systems of the children in our primary schools are being seriously undermined.

In so important a matter as the health of the rising generation we should welcome any additional knowledge that may be the outcome of this controversy; but the point of practical importance is how to maintain to the utmost the beneficial results of our educational system, and at the same time avoid the danger of over-pressure in individual instances or under specially unfavourable circumstances.

The provisions of the Mundella Code and the recent Instructions to Her Majesty's Inspectors ought to be fully carried out. In Article 8 of the Code managers are stated to be held responsible "for the care of the health of individual scholars, who may need to be withheld from examination or relieved from some part of the school work throughout the year." In Article 109 it is stated: "The inspector will also satisfy himself that the teacher has neither withheld scholars improperly from examination, nor unduly pressed those who are dull or delicate in preparation for it at any time of the year; and that, in classifying them for instruction, regard has been paid to their health, their age, and their mental capacity, as well as to their due progress in learning." The local managers are also considered the best judges of the special circumstances which render it inexpedient to require home lessons. But how are managers to judge of the health of individual children? The proposal that a monthly record of the height, weight, head and chest girth of all the children should be kept in every school is not likely to be adopted, on account of the enormous additional expense which it would entail; but it would not seem impracticable to draw up some simple regulations for teachers or managers which might enable them to detect an anæmic or neurotic condition or the incipient stages of nervous malady.

A guard ought to be set against those practices which tend to over-pressure. These are pretty well known to practical teachers. The London Board has during the last two or three years taken several steps in this direction. The teachers used to be paid partly from the Government grant, and thus had a pecuniary incentive to press forward the feeble, so as to insure their passing the examination. There were great difficulties in altering these arrangements, but it was accomplished at the close of last year. It is a common practice to prolong the hours of teaching, especially shortly before the inspector's visit; this was objected to by the London Board four years ago, and now is forbidden. Home lessons are left optional with the teachers and the parents. Improved physical exercises for girls have been introduced. The Education Department has been induced to diminish the excessive requirements of the Code in regard to needlework. Arrangements also are being made for relieving the pupil-teachers to a large extent from their labours in the schools.

It is to be hoped that one beneficial result of this discussion will be an increased perception of the necessity of variety in the subjects of instruction. In the words of Mr. E. N. Buxton, Chairman of the London Board, "It is monotony which kills; indeed, we look to a wholesome variety as a means of welcome relief." Happily the Code now requires "varied and appropriate occupations in infant schools;" and this is largely insisted on in the recent Instructions to Her Majesty's Inspectors. The dreary monotony of the three R's in the 1st Standard and in backward schools should be relieved by object-lessons or other interesting occupations, and literary studies should be balanced by the elements of science as well as by drawing,

[1] This matter is discussed in the *Statistical Journal* for June 1883 and June 1884.

singing, drill, and cookery or handicraft. It is a matter of common experience that whatever increases the vigour or quickens the intelligence of children enables them to acquire book-learning in a much shorter space of time. In whatever points educationists may differ, there will be a general agreement that the bodily senses of our young working-class population ought to be developed as well as their mental faculties, and that it is highly important for them at least to know something of the world in which they live and of the materials and natural forces with which they work.

J. H. GLADSTONE

THE DISTRIBUTION OF THE METEOROLOGICAL ELEMENTS IN CYCLONES AND ANTICYCLONES

Sur la Distribution des Éléments Météorologiques autour des Minima et des Maxima Barométriques. Par H. Hildebrand Hildebrandsson. Présenté à la Société Royale des Sciences d'Upsal le 10 Mars, 1883. (Upsal, 1883.)

WITH the publication of the first synoptic weather-maps in Europe and America about the middle of the present century, the scientific study of the great movements of the atmosphere and other phenomena of weather may be considered as having commenced. This method of inquiry soon taught us that in different parts of one and the same barometric depression or cyclone, very different climatic conditions prevailed. In the front part of the depression the weather is warm, moist, and clouded, whilst in the rear it is cold, dry, and clear. Further inquiry showed equally distinct types of weather characterising different parts of high-pressure areas or anticyclones. So close indeed are these relations that the study of weather resolves itself very much into an examination of the phenomena attending cyclones and anticyclones. If we could certainly prognose the distribution of atmospheric pressure over North-Western Europe on, say, Saturday next, we could for the same time forecast pretty correctly the weather over this part of the earth. Similarly, if we could forecast that the easterly tracks of the cyclones of the coming winter were to be south of the Channel, we could forecast a severe winter for the British Islands; and on the other hand if the path taken by these cyclones would be to the north of these islands, an unusually mild winter would certainly follow. Hence the supreme importance of any accession to our knowledge respecting cyclones and anticyclones. This is what Prof. Hildebrandsson's laborious and able paper does in various directions.

The direction and velocity of the wind as noted at Upsala at the surface of the earth, in the region of the lower clouds, and in the higher region of the cirrus, the temperature of the air, the amount of cloud, the frequency of rain, the transparency of the air, and the occurrence of fog are examined with reference to forty-three different sections or areas into which the author has partitioned cyclonic and anticyclonic systems according to the direction of the barometric gradient and the height of the barometer, three of these forty-three sections being the central areas of the cyclone and the anticyclone, and the space separating two cyclones which are not far apart.

As regards the direction of the wind it is shown that the angle made by the wind with the barometric gradient is greater in summer than in winter; greater at stations near the sea than at inland places; greater in cyclonic than in anticyclonic regions; and that the angle is the maximum, or the wind approximates most nearly to a circular course, when the gradient is directed towards the east, and the minimum when directed towards the west. The angle obtained for Upsala, which is nearly 50°, is greater than that obtained by Loomis for the United States, but less than what Mohn has found for Norway and Clement Ley for the British Islands. The observations made on three small islands were also examined, viz. Utklippan, a little to the south of Karlskrona, Wäderöbod, north-east of Jutland and a few miles off the Swedish coast, and Sandön, a low sand-bank about thirty-four miles north of Gothland, at which stations the angles are respectively 64°, 65°, and 74°. Here the influence of the sea on the angle made by the wind with the gradient is very striking, being about a half more at the strictly insular position of Sandön than at Upsala.

The angle is at the maximum in the three islands when the gradient is directed towards the east, and the minimum when directed towards the west, as at Upsala, and as Clement Ley has shown for England, Hoffmeyer for Denmark, and Spindler for Russia. One remarkable result is, however, shown with reference to each of the three islands, viz. the angle shows a well-pronounced secondary maximum when the gradient is directed towards the north-west. It is premature to attempt an explanation of the different degrees of the incurving of the wind upon the centre in the different parts of a cyclone, until similar results have been worked out for a large number of well-selected individual stations, and until a more definite knowledge is arrived at regarding the relative prevalence of ascending and descending aërial currents in the different sections of the cyclone and anticyclone.

The velocity of the wind is the minimum near the centres of cyclones and anticyclones, and in the middle space between the cyclones. From the central region of the anticyclone, the velocity of the wind increases as the barometer falls, and the maximum velocity is reached on approaching the calm central region of the cyclone. With respect to the gradients, the greatest velocity appears to occur when the gradient is directed towards the north and the least when the gradient is towards the west or the south-west.

In the region of the lower clouds, the wind takes a direction to the right of that of the wind at the surface of the earth. In other words, at this height the winds tend to follow the course of the isobars drawn for the sea-leve pressure, with however two noteworthy exceptions. When the gradient is directed towards the west, the angle exceeds 90°; but when directed towards the south or south-east, it is markedly less than 90°.

In the higher region of the cirrus clouds, the winds blow centrifugally from the region of the cyclone towards that of the anticyclone. The velocity is least in the vicinity of the central region of the cyclone, but it steadily increases as it approaches and flows over the region of the anticyclone. The centrifugal movement is greater in

the front than in the rear of a cyclone, where indeed the motion of the cirrus cloud approaches the direction of the lower clouds and of the wind at the surface of the earth. The direction of the cirrus immediately behind and over the centre of depression is in Sweden generally from north or west, but, from the exceptions which occur, it is evident that more observations and discussions of the results are required.

Fog is of most frequent occurrence when the gradient is directed towards the north and least frequent when directed towards the south. In the Kattegat, fog attains its maximum frequency in the region situated between the lowest and the highest pressures. At Upsala the clearness of the air is nearly independent of barometric pressure, there being, however, a greater tendency to mistiness in the air when the gradient is directed towards the west than other directions. Cloud and rain are most frequent with gradients to the south or west, and least with gradients to the north-east. In summer, they regularly diminish as pressure increases; but in winter, less regularly, inasmuch as the strato-cumulus, which are the most common clouds in this season, are most numerous in times of high pressure and occasionally bring with them slight showers of snow.

In winter, temperature is above the mean both in cyclones and anticyclones when the gradient is directed towards the west, and below it when directed towards the east. In the same season, temperature rises on all sides towards the centre of the cyclone; in other words, the thermometer rises as the barometer falls, and *vice versâ*. In winter also temperature is ordinarily above the mean in cyclones, but under it in anticyclones and in the region between two cyclones; in summer the reverse holds good—these results being due to the different effects of solar and terrestrial radiation in these seasons.

With reference to the distribution of temperature with height, Hildebrandsson has examined the observations made at the Puy-de-Dôme and at Clermont Ferrand, near the base of the mountain in connection with the cyclones and anticyclones in that part of Europe during 1877-82. The difference between the temperatures of the two places in winter attains the maximum in the vicinity of the centre of a cyclone, and the difference diminishes according as the barometer rises, and the minimum is reached near the centre of the anticyclone, where temperature on the mean is higher at the higher station, the difference in height being 3516 feet. In such investigations, this high-level station, as well as the high-level stations in the south of France, in Switzerland, and Austria, have the disadvantage of being almost always on the north-west slope of anticyclonic areas, the centres of which are situated in a south-westerly direction. It is on rare occasions that well-marked cyclones cross these stations, and still rarer that cyclones pass to the south-west of them. Prof. Hildebrandsson states his opinion that, for the prosecution of these all-important researches, Ben Nevis, with its low- and high-level stations, occupies what is, perhaps, the most favourable position in the world, seeing that it is situated in the track of the greater part of the Atlantic storms which sweep over North-Western Europe, and that the publication of the observations *in extenso* would be an important gain to science.

"*FLATLAND*"

Flatland: a Romance of Many Dimensions. With Illustrations by the Author, A Square. (London: Seeley and Co., 1884.)

WE live in an age of adventure. Men are ready to join in expeditions to the North Pole or to the interior of the African continent, yet we will venture to say that the work before us describes a vast plain as yet untrodden by any Fellow of the Royal Geographical Society, and teeming with a population of which no example has figured in any of our shows. A few years ago a distinguished mathematician published some speculations on the existence of a book-worm "cabin'd, cribb'd, confin'd" within the narrow limits of an ordinary sheet of paper, and another writer bewailed "the dreary infinities of homoloidal space." A third remarks, "there is no logical impossibility in conceiving the existence of intelligent beings, living on and moving along the surface of any solid body, who are able to perceive nothing but what exists on this surface and insensible to all beyond it." How delighted Prof. Helmholtz will be to find, if this Flatland writer is worthy of credence, his conjecture thus verified. "Flatland" is not the real name of this unknown land (that secret is not divulged), but it is so called here to make its character clear to us Space-denizens. It is a noteworthy fact that one at least of the Flatlanders expresses himself in remarkably correct English, and singularly after the manner of an ordinary Space-human being; and further, though—we regret to have to record it—as a martyr in the cause of the truth of a third dimension, he has spent seven long years in the State jail, yet these memoirs have in some mysterious manner found their way into our hands. There is hope then that some one of our readers may yet expatiate in the broad plain, though the penalty will be, we fear, that he must first become as flat as a pancake and then see to it that his configuration (as a triangle, square, or other figure) is regular. This latter is a *sine quâ non* in Flatland, because, whatever you are, your configuration must be regular, or woe betide you, and you will shuffle off your mortal coil incontinently.

We will not stop to inquire how this and that have come about, but will endeavour to lay before our readers some of the features of this (to us) new world, though we are informed that it has just entered upon its third millennium.[1]

In Flatland there is no sun nor any light to make shadows, but there is fog. This, which we on this earth consider to be an unmitigated nuisance, is recognised in that other world "as a blessing scarcely inferior to air itself, and as the Nurse of Arts and Parent of Sciences." If there were no fog, all lines would be equally distinct, whereas under present circumstances, "by careful and constant experimental observation of comparative dimness and clearness, we are enabled to infer with great exactness the configuration of the object observed." It is a necessity of Flatland life to know the north (for instance, it is a point of good breeding to give a lady the north side of the way); this is determined in the absence

[1] From the secret Archives it appears that at the commencement of each millennium a Sphere descended into the midst of the Council of Circles proclaiming the great truth for the attempted teaching of which our author is in bonds.

of any heavenly bodies by a novel (we speak as a Space-denizen) law of Nature, viz. the constancy of an attraction to the south: however, in temperate regions the southward attraction is scarcely felt, but here again Nature comes to the Flatlander's aid. If he is in an inhabited region, the fact that the houses (mostly regular pentagons; squares and triangles are only allowed in the case of powder-magazines, barracks, and such like, for sufficient reasons) have their roofs towards the north, so that the rain, which always comes from that quarter, may run off and not damage the houses, will help him to get his north point. If, however, he is out in the country far away from trees and houses, there is no help for him until a shower of rain comes. We must now give some description of the inhabitants. The women are all straight lines; the men are other regular figures (if there be hopeless irregularity, which the hospitals cannot cure, then the man is put to death). The lowest orders, policemen, soldiers, and the *canaille*, are isosceles triangles, their mental calibre being determined by the largeness or smallness of the vertical angle. It is possible for an isosceles triangle to be developed into an equilateral triangle, or the offspring after a few generations may be so developed: in this class are the respectable tradesmen. The professional men and gentlemen are Squares—our author is a lawyer—and Pentagons. The Circles (that is, approximations more or less closely to that figure) are the nobility.

Another law of Nature in Flatland is that "a male child shall have one more side than his father, so that each generation shall rise (as a rule) one step in the scale of development and nobility." Our author, as appears by the drawing on the cover, has four pentagonal sons and two hexagonal grandsons. We do not clearly gather where the one eye (for Flatlanders appear to be monoculi) is situated, and how locomotion is effected we are not told. It can hardly be by such means as were once suggested by Prof. Clerk Maxwell, for in Flatland you must go steadily forward or dire may be the disaster you will inflict upon your neighbour. There seems to be no lack of Board schools, and there is at least one university, that of Wentbridge (we had by force of habit written Cambridge), where instruction is given in mathematics. A knowledge of this branch of study is obligatory, for since a Flatlander's eye can only move in his world-plane, all the objects, human and otherwise, even the circular priests, appear to be straight lines, and the figure-angles have to be, at any rate approximately, correctly guessed at sight.

Before we close our notice we must return to the description of the womankind. The women we have said are straight lines, hence they are very formidable, for they are like needles, and what makes them more to be dreaded is that they have the power of making themselves practically invisible, hence a Flatland female is "a creature by no means to be trifled with." There are, however, certain regulations in force which diminish the dangers resulting from having a woman about the house. There is an entrance for her on the eastern side of the house, by which she must enter "in a becoming and respectful manner"; she must also, when walking, keep up her peace-cry, under penalty of death, and if she has fits, is given to sneezing, or in any way is liable to any sudden movement, there is but one cure for such movements, and that is instant destruction. Though involuntary and sudden motions are thus summarily dealt with, yet if she is in any public place she must keep up a gentle "back-motion," and thus she is less liable to be invisible to her neighbours. Happily fashion exercises its potent sway in Flatland female society, as elsewhere, for we learn that "the rhythmical, and, if I may so say, well-modulated undulation of the back in our ladies of circular rank is envied and imitated by the wife of a common Equilateral, who can achieve nothing beyond a mere monotonous swing, like the ticking of a pendulum." Owing to their unfortunate configuration they are inferior in all good qualities to the very lowest of the Isosceles, being entirely devoid of brain-power, and they have "neither reflection, judgment, nor forethought, and hardly any memory." This is but a poor account, but we must bear in mind that it is an *ex parte* description by a Square who may at some time have suffered a disappointment at the hands of a lady. We shall be glad (though we can hardly expect such a result)—now that tidings have come from this little-known country—if some female will favour us with her view of the state of matters in Flatland. At birth a female is about an inch long, a tall adult woman reaches to about a foot. The length of the sides of an adult male of every class may be said to be three feet or a little more.

The book consists of two parts—*This World*, *i.e.* of Flatland, in twelve sections, and *Other Worlds*, in ten sections. The whole is very cleverly worked out, and many passages descriptive of events in the past history of the country at times force upon one the thought that after all the book may have been compiled by a Space-denizen, and that he is quietly laughing in his sleeve and saying, "de te Fabula narratur." However this may be, Flatlander or Spacelander, there is a slip in the note on p. 64, and for "Flatland" should be read "Spaceland."

We commend "A Square's" book to any of our readers who have a leisure hour from severer studies, and we believe when they have read it they will say "the tenth part of the humour has not been suggested" by our description.[1]

R. TUCKER

OUR BOOK SHELF

The First Principles of Natural Philosophy. By W. T. Lynn, B.A., F.R.A.S. Second Edition. (London: Van Voorst, 1884.)

IT is a little difficult to see what useful purpose is served by this work, or why a second edition should be called for, seeing that it is neither of the popular nor yet of the properly scientific order of text-book. Its modes of regarding and describing the facts of dynamics are antiquated and incorrect, and it is extremely barren in numerical illustrations of the kind most helpful to elementary students. The author begins by telling the reader that "a pulling force takes the name of a tension," whilst "a pushing force" takes "that of a thrust." He then gives in abbreviated form Duchayla's proof of the parallelogram of forces, "because it is the foundation of the whole theory of statics," in spite of its essential faultiness in requiring more assumptions in the course of the argument than if the simple rule of compo-

[1] We may mention as specially humorous the chapters in which the Square is initiated into some of the mysteries of tri-dimensional space by the spherical stranger.

sition of vectors were assumed outright. The author is probably now the only surviving writer on dynamics who persists in muddling up force and acceleration by calling acceleration (a purely kinematical quantity in itself) an "accelerating force," and he adds to the muddle by writing $v = ft$ where all modern writers would put $v = at$. What the student is to understand by "a force capable of generating in one second a velocity represented by DE" (p. 27) is difficult to see, when the mass on which the force is to act is nowhere stated, and when it is not even stated or hinted that there is any mass at all to be acted on. On p. 41 the author states that "in this country the ounce avoirdupois is so taken that one thousand of them will just balance a cubic foot of distilled water." This is not so, at least in *this* country, for the mass of the ounce depends on the standard pound, and this was established without any reference to a standard volume of water. The definition is wrong; the fact it states is a mere coincidence; and the coincidence itself is not exact: a cubic foot of water does *not* weigh 1000 ounces. On the same page the author tells the reader to ascertain with respect to a certain mass the velocity which "a given pressure or impulse" will impress upon it; "the mass being inversely proportional to this velocity." The confusion between *pressure*, which cannot be expressed except in terms of force divided by area, and *impulse*, which is expressed as force multiplied by time, is truly amazing. Is time the reciprocal of an area? Again, on page 42 the author is speaking of a certain force capable of sustaining a certain weight for one second of time, and he says "it would require twice as powerful a force to enable it to resist the action of gravity for two seconds, three times for three, and so on." This is news indeed. In the section on hydrostatics, no sooner has the student learned that a pressure of one pound per square inch is equal to 100 lbs. per 100 square inches, than he comes to such a statement as the following (p. 52): "The pressure therefore exerted by a mass of fluid upon the bottom of a vessel containing it is proportional to the area of the base," &c. Here the author jumps, without one word of warning to the student as to his change in the use of words, from using the word pressure in its proper sense of so many *pounds-per-square-inch*, to using the word in the sense of so many *pounds*, in which case it is no longer a 'pressure" but a "force." It may be said perhaps that these things are but slips of the pen. Perhaps they are; but in a teacher who undertakes to write a text-book of "first principles" slips of such a kind are unpardonable. No such confusion of thought would be tolerated in the pupil who had read Wormell's "Dynamics," or Lodge's "Mechanics," or Maxwell's "Matter and Motion," or Thomson and Tait's lesser volume. If Mr. Lynn does not intend his text-book to be cast aside as worse than useless, he must at once correct blundering modes of thought that can only mislead the student.

Éléments de Mécanique, avec de nombreux Exercices. Par F. I. C. Pp. 282. (Paris: Poussielgue Frères.)

THIS is the concluding volume of a series of elementary class-books on pure and applied mathematics issued by l'Institut des Frères Écoles chrétiennes, a French Society which showed in the Technical Schools at the recent Health Exhibition a noteworthy collection of specimens of work done in their schools, along with the educational apparatus used therein.

The character of the book before us harmonises with the evident sympathy of the Society with the manufacturing industries of the districts in which their schools are situated. We are furnished with an introduction to applied as well as to theoretical mechanics. There are good diagrams and descriptions of weighing-machines, cranes, and other lifting-tackle in the section on statics; the longest chapter in kinematics is concerned with the simpler forms of mechanism; and in dynamics there is a full discussion of the principle of work and its application to mechanics.

The text is clear, as far as it goes; but we think the general exposition of the theory too concise, many important points being relegated to the exercises at the end of each chapter.

There is a good collection of problems filling the last fifty pages of the book, but no examples are worked out in the text, and there are no results given to any of the exercises. Clearly, pupils using the book would require a good teacher at hand, who could devote ample time to the subject.

We should wish to see a book like this with a few select students, but, having regard to general class instruction, we do not think the mode of treatment a happy one. We feel called upon, however, to give a cordial recognition to the expansion in the direction of technical instruction, to the liberal supply of good diagrams, and to much freshness of treatment, both in text and examples, in the work before us. A. R. W.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Chemical Research in Great Britain

AT the anniversary meeting of the Chemical Society held March 31, 1884, the President read an address to the Fellows, which contains a series of remarks upon the prosecution of original research in England requiring some notice, particularly as a separate issue of the address has been circulated by the author. Attention is directed to the fact that we have an increased number of laboratories in Great Britain[1] and greater facilities for the prosecution of research through the aid of the Government grant and the Chemical Society's fund. Notwithstanding this the startling and anomalous fact is to be observed that the number of papers read before the Society is declining year by year.

After speaking in terms of praise of the degree of Doctor of Philosophy of Germany, which necessitates the prosecution of some original investigation, there follow some remarks which read like a serious reflection on a number of professors who have won distinction through unremunerative devotion to scientific teaching and research.

"The past neglect of research will, it is to be feared, have a more lasting influence on the progress of chemistry in this country than may appear at first sight, and in this way. Those who have been students in laboratories where the importance of this kind of work is not recognised, advance in their positions, becoming assistant demonstrators, &c., and eventually professors, and as they have not learnt to practically realise the value of research by being in the habit of conducting it themselves, or of seeing others do so, when they become professors they will naturally not encourage students to undertake it in their laboratories, and it is to be feared that we are already suffering in this way, and that this is one of the causes why the new laboratories which have been opened are doing so little to add to our store of fresh knowledge."

It will be questioned whether such a statement can be justified when it is mentioned that there happens to be lying on the table before the writer four reprints of papers recently received from the respective Professors of Chemistry in four of the new colleges; three of these memoirs are published in the *Philosophical Transactions* of the Royal Society, while a fifth occupant of one of the newly created chairs not long since received the Longstaff Medal. The whole subject seems scarcely to have been so well considered as to lead to a just appreciation of the cir-

[1] The term used is the United Kingdom, which includes Ireland. There has been no increase in the number of laboratories in Ireland, and only an increase of one in Scotland.

cumstances which give rise to unfavourable comparisons between scientific work in Great Britain and on the Continent.

But let us deal with the decline in the number of contributions to the Chemical Society. In 1880-81 there were 113 communications; in 1881-82, 87; in 1882-83, 70; and in 1883-84, 67. To what may this decline be assignable? In the first place the Chemical Society is not the only body in the United Kingdom which publishes papers on chemistry; there are the Royal Society of London, the Royal Society of Edinburgh, and five others, including the important Society of Chemical Industry. There are two societies in Dublin, but in this discussion Ireland will be left entirely out of the question. Causes not easily definable may lead to the transfer of authors' works to one or other of these bodies instead of to the Chemical Society. In fact these figures inform us that as the Society of Chemical Industry sprang into being and increased in importance so did the number of contributions to the Chemical Society diminish, and those to the younger body increase. We find that in 1883-84, the second year of its existence, there were sixty-eight papers read at the meetings of the Society of Chemical Industry, and the President will probably have to congratulate the members upon a still further increase at the next anniversary meeting. This is not all; the number of papers is no criterion of the excellence of the work done, and it may be maintained that the importance of the published communications has very distinctly increased, and if this be admitted it is self-evident that with increased elaboration, provided the same amount of work be expended, numerical decline must follow. In comparing the number of papers published in the *Transactions* of the Chemical Society with those in the Berlin *Berichte*, there is also an element of unjust reckoning, inasmuch as the latter volume includes the work of chemists not only distributed throughout the whole German Empire, but of many natives of eight other countries of Europe, occasionally a contingent from America, and even one or two from England. A strict examination will show that our shortcomings are scarcely so considerable as they appear from the President's representation.

Let us now consider what influence on original work may be expected from an increased number of laboratories and colleges. It is made to appear as if the fault which renders comparisons unfavourable to us lies entirely with the teachers. This is unwarrantable because, for the amount of instruction given, the proportion of professors and lecturers in Great Britain is much smaller than in Germany. Courses of lectures on theoretical chemistry—inorganic and organic—metallurgy, and applied chemistry, are not unusually required from one professor, who sometimes in addition is expected to lecture at night to artisans. In one or two cases he has to treat of physics, and is styled the Professor of Chemistry and Physics. Such labour would never fall to the lot of any German professor. For the sake of brevity all reference to the paucity and insufficiency of the endowment of the chairs may be omitted, as likewise the motives for study which influence the attendance in the new colleges.

It may well be doubted whether the President of the Chemical Society had earnestly sought to make himself acquainted with the course of instruction pursued in most English laboratories, and realised the difficulties in the prosecution of research by students which are known only to teachers. Medical students, for instance, pay their fees for a certain well-defined course of instruction, and always see that they get it. The lecturers and professors in other colleges, such as those recently established, would neglect their duty if they did not follow out the programme of studies drawn up by the respective Boards and Councils. The town councils, associations of manufacturers, and public-spirited gentlemen who establish the new colleges have been taught to believe that our manufactures and scientific industries are languishing for want of technical education, which must be supplied to masters, superintendents, foremen, and workmen. Their schemes of education are based on the requirements of such a class of students, and they are bound to comply with the demands made upon them. Hence it arises that a three years' course of study is devoted to mathematics, mechanics, drawing, physics, chemistry, and engineering. Chemistry in England is either a branch of general education, a professional, or a technical study, but seldom is it pursued for its own sake. From upwards of 1000 students taught in the laboratories of a single college during a period of nine years, only seven men can be counted who prosecuted their studies with any idea of making themselves chemists, and of these, five were the authors of researches pursued during their college career, which were published in the Chemical Society's *Journal*.

In the German Empire there are twenty-two Universities, all departments of the State, with professors, lecturers, demonstrators, assistants, buildings, and laboratory equipments provided and maintained by funds from the respective Governments. There are about two thousand teachers and twenty-five thousand students annually pursuing all branches of learning. Science, and experimental science especially, is valued to the same extent as classical and mathematical training in England; chemistry especially receives great attention, as is shown by the fact that the above figures include one hundred and twenty professors of chemistry, sixty of whom are "ordentliche Professoren." The cause of this has been attributed by some to the teachings of Liebig and those of his school. The result is that a student occupies himself with the most recondite branches of chemistry, physics, and cognate subjects, without having in view any immediate application of his knowledge or research either to the requirements of a professional career or those of a scientific industry. This is shown by the period spent at the University being longer than is necessary for such a purpose. Tradition has placed the learning of the schools of Oxford and Cambridge on a higher platform than that of science, and we cannot alter in thirty years that which has existed in men's minds for more than three centuries,[1] unless indeed we can call to our aid an intellect like that of Liebig placed in a position of great influence. It would, however, be a national misfortune if other branches of learning were to suffer for the benefit of science.

The recently-established colleges in the manufacturing districts differ from the Universities, and are more nearly allied to the special schools or Polytechnics of the Continent; but, in addition to providing the education of such establishments, they have to perform the functions of University colleges, of medical schools, and frequently also of superior mechanics' institutes, generally with a staff inadequate for the purpose. For the most part knowledge is acquired in such institutions only to serve as an aid to improving manufactures. There are on the Continent, not counting France, eleven Polytechnics, or high schools, built at a cost of not less than three millions sterling, and maintained by an annual expenditure of 200,000*l*. In "Les Allemands," by Le Père Didon, it is remarked that the prosperity of highly-cultivated nations depends upon the prosperity of the special schools and the Universities together, but there is a danger when the prosperity of the former leads to a decline in the popularity of the latter. In the work quoted, England is cited as an example of the inconveniences that arise from a want of equilibrium between professional education and the more theoretical and speculative teaching of the Universities. The dominating studies of classical literature, pure mathematics, philosophy, history, and theology of Oxford and Cambridge cause students of the middle class too frequently to pass at once to the professional colleges of medicine, engineering, &c., instead of educating professional men up to that level of general knowledge without which the most able specialist is wanting in a great essential to success in life.

That originality of thought is fostered and cultivated at the German Universities is an undoubted fact, but the requirements of the degree of Doctor of Philosophy cannot be entirely credited with this; it is rather that which is not required which is so advantageous to students. It is the *Lehre und lern Freiheit* which professors and pupils both enjoy; the professor has time for thought, and is not hampered by having to consider whether that which he teaches must be a suitable preparation for the pupils' various examinations, while the student, on the other hand, is not harassed by having to devote time and attention to uncongenial studies.

On the Continent the motive for scientific education is mental culture, while in Britain it is utilitarianism; while the former tends to the *advancement of learning*, the latter involves nothing further than the *diffusion of knowledge*. Hence the utilitarian principle neutralises in a great measure the advantages of an increased number of colleges, improved laboratories, and possibly of money-grants in aid of research.

The debased utilitarian view of the advantages of studying science is spread throughout the whole of this address, and it would be deplorable if all the presidents of the learned societies

[1] Bacon says ("Aphorisms," Book I. xc): "Again, in the habits and regulations of schools, universities, and the like assemblies, destined for the abode of learned men and the improvement of learning, everything is found to be opposed to the progress of the sciences.

preached an annual sermon from the same text. It is certain that the sympathies of the public would be alienated; and if those hearers who are taken to task were to follow consistently the lesson inculcated, they would occupy themselves entirely with objects of pecuniary gain instead of providing the discoveries which our manufacturers are so much in need of, or advancing learning by their contributions to the *Philosophical Transactions*.

W. N. HARTLEY

Our Future Watches and Clocks

IN reference to the note on this subject in NATURE (p. 36), it appears to me that to any radical change in dial-division there exist many objections, of more or less weight, over and above those already enumerated. In regard to—

(*A*) *Striking the hours.*—(1) It is said that "public clocks . . . could not go on to twenty-four." The same would apply to private clocks as well, as the higher numbers would be struck during the—to children and many others, sick or well—early hours of sleep, when greater disturbance from house clocks than at present occurs would be quite unendurable. The counter-advocacy of silent house clocks would scarcely meet the case.

(2) The alternative suggestion of "one stroke only at each hour" would do away with one important function of public clocks, that of marking to watchless people the exact hour. Persons abed, lonely watchers, and field-labourers, commonly depend upon the church clock for information which could only be acquired otherwise with much discomfort.

(*B*) *The* 24-*division plan.*—(3) That no diminution in "the angular motion of the hand" during any given time should be brought about seems most vital. The time of day is often obtained from far-distant clocks, and is even at present not easy to decipher readily, especially under circumstances of inadequate ight or visual power.

(4) Similarly, in the case of any slight looseness in the hands—a commonly-neglected chronometric infirmity—it would be harder than ever to decide at a glance what hour is indicated.

(5) It will be observed that the adoption of this plan would almost necessitate half-minute arcs.

C) *The double* 12-*division plan.*—(6) Inasmuch as the presence of two concentric circles of figures of undiminished size would shorten the clear effective length of the hands, the arc subtended by the hourly angle would be diminished by much the same extent as in the previous plan (*B* 3), and a similar objection would apply.

(7) The presence, in any form, of twenty-four symbols, in addition to the maker's name and the like, in the dial area, especially in ladies' time-pieces, would be eminently confusing, and restrictive of instantaneous decision as to what the time may be.

8. Even if, to obviate all this—a point suggested by the statement that "persons probably pay small attention to the figures"—a single circle of twelve conventional symbols, identical or not, such as a radial arrowhead, were adopted to indicate the a.m. and the p.m. hours in their turn, one would have to undergo the added mental labour of deciding the actual *number* of the hour.

(9) In any case the introduction of a "0" hour, unless we are to adopt railway phraseology, would be most awkward, and in the "double 12-division plan" the transition at noon and midnight from one circle to the other would not be a simple sequence.

Finally, the question arises whether the now common time-pieces, in which the hands are either replaced or supplemented by a series of peep-holes, wherein the minute, hour, and even week-day for the time being, are consecutively displayed, would not aid the introduction of the twenty-four hour system into rough general use. The main disadvantage of abolishing the hands is that one would lose an actual picture suggestive of the time which will elapse between the present and any point in the near future. For all purposes for which closer chronometric accuracy is required, the above stumbling-blocks to change in dial-division, arising out of the pressing value in ordinary life of the ability to tell the time swiftly, and without undue mental effort, would be swept away.

ERNEST G. HARMER

88, Buckingham Road, N., November 19

As regards the practical question how clocks are to be made to strike if the dial is to show twenty-four hours, I have a suggestion to make.

But firstly, the convenience of beginning the day at midnight is evident, as the early morning hours are those which it is most useful to have indicated to the ear, and our clocks may continue to strike from 1 a.m. to 6 as now.

The inconvenience of having to count any number of strokes above six is so great, and doing it so tedious, that most persons break down in attempting it with a slow-striking clock; and I think that there is a good deal to be said for the system, which obtains in some places where the hours are still reckoned as twenty-four, of beginning afresh at the end of every six hours, and denoting 7 and 13 as 1, &c. This plan would make very little or no change.

But what I wished to suggest is: That clock-makers should make the clocks to beat the strokes in pairs; *e.g.* two strokes and a rest + two strokes and a rest + one stroke, would be 5. This would be counted as easily as 3. Moreover, there would be no occasion under ordinary circumstances to count the strokes at all; whether the hour was *odd* or *even* would be all it was necessary to learn for one to know which hour it was of the twenty-four. One may, for instance, in the morning doubt whether it is 10 or 11, or whether it is 11 or 12, but one rarely doubts whether it is 10 or 12. And on the principle I recommend, the last stroke of the clock being single or double would decide the matter. One would not even have to attend to it. I contend that under the present system it is impossible for a person with only ordinary patience to discover whether a clock strikes 11 or 12.

If you think anything of this suggestion, which I have always thought myself to be a fair solution of a difficulty, I shall be glad if you would insert it in your paper.

R. B.

Lightning-Conductors

IN the *Edinburgh Review* of last July many of your readers will probably have noticed an article on "Lightning-Conductors," written somewhat strongly from the point of view of an advocate of the apparatus thus popularly designated. Perhaps a few words of comment on this paper from a rather different aspect may not be without interest to those who are able and willing to treat the subject with unprejudiced minds.

In the reviewer's narrative of the history of lightning-rods he omits all mention of Franklin's initial letter of September 1, 1747—that letter in which the great discovery of the power of points is given to the world. But it is abundantly evident from his subsequent letters of 1749 and 1750, in which he definitely forecasts the invention of rods, that it was to his knowledge of this power—and of this power alone—that he owed the idea of these instruments. In other words, his original conception was purely that of an apparatus for *preventing* the occurrence of a lightning-stroke at the place where the rod was erected. Now, if I am not mistaken, the reviewer from first to last never alludes to this all-important function. It is true that Franklin himself afterwards fell in with the curious supposition that these rods acted as "conductors" of a stroke. But (so far as can be judged from his letters) this was not till September 1753, at which time most of the European scientific men, themselves either ignorant or sceptical of the preventive power of points, had fully adopted the invention and had invested it with the theory, that has ever since been accepted, of its being a means of "conducting" past the building a stream of fiery matter (denoted as "electric fluid") descending from the clouds to the ground. Now it is evident that nothing can conduct the agency known by us as "lightning" without first being struck by it; and it is also manifest that, in order to be so struck, an object must present some "attraction" to the stroke. This attraction—this necessary first step to conduction—allowing for the nonce that an explosion such as constitutes a lightning-stroke *can* be conducted—is a matter that usually (and not unnaturally) is treated by those who believe in lightning-rods with some little reticence. I therefore think it is but fair to give credit to the reviewer for the open and honourable manner in which he enunciates his views of the true function of lightning-rods. He says (p. 40):—"Conductors provided by engineering art are *intended* to be struck, but struck in such a manner as to govern the lightning and to render the heaviest strokes harmless." There is no beating about the bush. He admits that his conductors are purposely fixed on a house in order to attract a stroke to that house with the view of afterwards rendering the effects of the explosion nugatory. Now the very essence of the opposition that has been made to the use of these conductors lies in this very fact of

attraction—and in one other fact, which is this. It is absolutely impossible to prove that *any stroke at all* would have occurred at the house if the attractive conductor had not been present. Granted, we (opponents) say, that your conductor, if in good order, *may* be the means of averting the terrific force of the explosion from the non-conducting materials of the building when once the stroke has been developed, we nevertheless prefer that our houses should receive *no stroke at all*. We infinitely prefer to run the extremely unlikely chance of ever being visited by a lightning-stroke to the practice of deliberately inviting such a stroke to our houses, and of trusting to the excellence of the rod-manufacturer's arrangements to avert any portion of its effects from the inmates and the structure.

Holding, then, as we do, that the principle of the lightning-rod, *quâ* its necessary exposure of additional elevated metal on a building, is vicious, and that nothing of a beneficial nature due to the preventive power of its point (if it have one) can obliterate this dangerous tendency, the undoubted disadvantages of the system, due to the defects in practice that habitually accompany the employment of rods, appear to be minor points. But the reviewer's reasoning on this branch of the subject is worthy of remark. He says (p. 52): "The failures incident upon defective work—as all unbiased and properly-trained thinkers are aware—are amongst the weightiest of the arguments that tell in favour of the employment of conductors." This sentence is wholly beyond my own reasoning power. Because (*cæteris paribus*) an apparatus is liable to failure on account of being defectively constructed, *therefore* it should be employed! He goes on to say:—"In a very large majority of the cases in which accidents have occurred to buildings which have been furnished with lightning-conductors the mischief has actually been traced by competent inquiry to some easily recognised fault or deficiency of construction." Allowing that even in *all* cases in which these disasters had occurred this statement were true, what does it show? Why, simply the very cheap sort of perception known as *wisdom after the event*. The manner in which, after the blow has happened, ingenious excuses are constantly made for the unfortunate conductors, which previous to the event had never been found fault with, is to the opponents of rods one of the most amusing and least edifying circumstances that environ the use of these instruments. But I would now venture to submit a few statistics derived from researches specially made by me during the last five years in regard to strokes and accidents in connection with lightning-rods. Up to date I have collected the fullest details of 320 well-authenticated cases. In 204 of these, or 64 *per cent.*, injuries either to rods, constructions, or persons, occurred. In 151 cases, or 47 *per cent.*, there were injuries either to constructions or to persons. Out of these 151 incidents, 71 contain in their records no allegations as to the existence of faults, either in the rod or in its "earth," until *after the event*, and the remaining 80 furnish no record of such faults being found *either before or after the event*. And indeed the whole of the results of my researches afford evidence (and especially in regard to the "earths" of rods) that failures and accidents more frequently happen with rods in what is deemed good order, than with those considered after the event to have been in bad order.

The reviewer in his enthusiastic advocacy of lightning-rods advises his followers not to be content with single, or even a few, rods on their houses, but to cover them with "a broadly-cast net of metallic meshes and lines." And he concludes with the following sentence:—"The free and frequent use of the testing galvanometer is the natural consummation of the beneficent work which was initiated by Franklin 130 years ago. Without this instrument the lightning-conductor is a hopeful and very generally helpful expedient. But with the galvanometer it is now assuredly competent to take rank as a *never-failing protection*." These *dicta* aptly conform with the reviewer's tactics in respect of the practical question of the *cost* of lightning-conductors. Here again, as in the case of the preventive power of points, he never mentions the subject. He seems to think that persons of common sense are capable of throwing "a broadly-cast net of metallic meshes and lines" of the purest copper over their houses, and of entertaining at frequent intervals the services of electrical testers to attend to these meshes and lines, without first counting the cost. He is perhaps unaware that (according to Sir William Thomson) the Glasgow manufacturers think it cheaper to insure their factories rather than to employ lightning-rods. But surely in regard to the statement that the use of the galvanometer makes the lightning-conductor a "never-failing protection," there is some little obscurity in the premises and conclusions. It is well known that rod advocates recommend the use of the galvanometer principally in order to test the resistance of the rod's "earth." If this resistance should prove to be above a certain standard, they say that the rod is not only useless, but dangerous. How is the mere fact of the *knowledge* that a rod is useless, or that its earth-resistance is too great, a "never-failing protection"? And what remedial measures can possibly obviate the dryness of the ground? One might as well say that the services of a physician who, having tested his patient's state of health, should tell him that he was in a bad way, and should then dismiss him, constituted a "never-failing protection." In the case of the rod the only protective feature appears to me to lie in the probability that most persons who were also "unbiased and properly-trained thinkers," on being informed that the galvanometer had demonstrated their rods to have a too great "earth" resistance, would immediately pull them down. But obviously this is hardly the reviewer's meaning. ARTHUR PARNELL

Government Scientific Books

SHORTLY after the commencement of the publication of the "Scientific Results of the Voyage of H.M.S. *Challenger*" by the Government, the late Mr. T. C. Cobbold, M.P. for Ipswich, inquired in the House of Commons whether, inasmuch as this expedition was undertaken with the nation's money for national scientific purposes, a copy of the volumes as published would not be presented to the public libraries supported by public rates, &c. The Government reply was that the expense of supplying the work gratis to such libraries in the different towns throughout the country would be too large.

I should like to ask whether it would have cost anything like the 87,500*l.* which the Government has recently paid for only two pictures from the Blenheim collection, and whether the ratepayers throughout the country have not a far greater right to be supplied (through their libraries) with the opportunity of seeing and studying the results of their own scientific expeditions than the remote opportunity of seeing these two 87,500*l.* paintings at Kensington.

I see by your advertisement that the tenth volume, at 50*s.*, of the "*Challenger* Reports" is just published. What chance have thousands like myself of ever seeing them. Our public museum library cannot afford to purchase them, though I have little doubt but that our town, with its 50,000 inhabitants, has more than paid for a copy of the Reports in its share towards the expense of the Expedition and the publications resulting therefrom.

As a country ratepayer I must protest against this centralisation of all the great works in art and the benefits and results of scientific expeditions in London. Some of your correspondents have complained that such *national publications* are not supplied to great national libraries abroad, but how is it that even we who have had to pay for them cannot ever get a sight of the results of such interesting and important national scientific expeditions. "Cannot afford it" is the Government reply, but how then can they afford 87,500*l.* for two paintings for the national galleries? I do not grudge the expenditure of the people's money for the latter, only when set off against the "cannot afford" for the former. W. BUDDEN

Ipswich, November 18

P.S.—I have the two volumes of Sir C. W. Thomson's "Voyage of the *Challenger*," but they have only tended to create a greater desire to see the complete "Government Reports," a wish, alas, which, from the expenditure of the 87,500*l.* for pictures by the Government, is further off than ever.

Peculiar Ice Forms

ABSENCE from town prevented me from seeing NATURE of November 6, in which there is a letter (p. 5) signed B. Woodd Smith with the above heading.

Possibly Mr. Smith's very ingenious explanation of the cause of the columnar form of the shallow stratum of ice he so well describes may be the correct one; yet perhaps I may be permitted to offer a very different solution of the difficulty connected with this very curious ice formation.

I have frequently noticed, both on lakes having deep water

and on those so shallow as to freeze to the bottom, that when the winter ice had nearly all thawed away, the remaining ice assumed the basaltic or columnar form, which on the deep-water lake could be walked over with perfect safety in the early morning, being then perhaps six or eight inches thick, and apparently quite solid, but which all disappeared a few hours afterwards in a magical manner, the columns having become very rapidly detached, especially if there was a fresh breeze, and, falling over on their sides, became invisible, and drifted to the lee side of the lake. This often led to a very general but wholly erroneous belief that the ice had *sunk*.

The question may be very naturally put: What has all this to do with "peculiar ice forms" on dry land?

The foregoing particulars are mentioned to show that ice in wasting away assumes not unfrequently the basaltic form.

I believe that the bank on which the peculiar ice was noticed by Mr. Smith, and described by him as bare of vegetation, is usually covered in winter by a deep snowdrift, and that, towards spring and later, pressure and the percolation of water from the thawing surface converts the lower stratum of snow—still colder than the freezing point—into ice. May not this ice, when nearly all wasted away, assume, as it does on the lakes, a basaltic structure?

May not the division of this four inches of ice "into four distinct layers—the columns of one layer being readily detached from those underneath"—be accounted for by what I have found to take place in snowdrifts, as I shall attempt to explain.

In building snow-huts there are two requisites essential for perfection in this kind of architecture. First, the snow has to be packed so firmly by the force of the wind as to be hard enough to walk over without sinking in it; secondly, the required depth of from fifteen to sixteen inches must be the formation of one and the same snowstorm and gale of wind. If this is not so, and the required depth of fifteen inches has been the result of three separate snowstorms, the blocks of snow, when sawn out, would not cohere, but break into three narrow strips of four or five inches each, which would render hut-building in the proper *artistic* manner and with rapidity (an important point in very cold weather) impossible.

These separate layers of ice noticed by Mr. Smith may possibly be the small remains of four separate and distinct snowstorms piled one above the other, which I know do—whilst in the form of snow—retain their individuality for the whole winter, although super-imposed the one upon the other.

The layer of "dirt" which Mr. Smith, from his point of view, very naturally supposes to be evidence that the mass of "peculiar ice" was pushed up from below, may be very easily otherwise accounted for.

In all gales with drifting snow in the Arctic, especially when there are high steep lands to be passed over, part of the ground is cut away by the driving snow in the form of fine powder or dust, and is carried sometimes a long way until deposited with the snow in some sheltered part.

This dust is small in quantity as compared with the bulk of snow, and is scarcely discernible when mingled with it; but when greater part of the snow melts, the dust shows as a very perceptible coat of "dirt" on the surface, which I consider has come down from above instead of being "pushed up from below" out of the ground as Mr. Smith believes to be the case.

Fly-Maggots Feeding on Caterpillars

IN reply to Dr. Bonavia's note on the above subject in NATURE for November 13 (p. 29), I beg to inform him that the larvæ of the house-fly are often internally parasitic on the larvæ of Lepidoptera. I have bred them in large numbers from *Vanessa io* and *Saturnia carpini*, also from other species more sparingly. Nor is this the only species of Diptera that infests Lepidoptera. F. N. PIERCE

Birds'-Nest Soup

IN NATURE of July 17 last (vol. xxx. p. 271), just received, appears an article on "Birds'-Nest Soup," which contains the statement that "the nests of the *bats*[1] and swifts were seen hanging in clusters from the sides and roof." That the addition of the "*bats*" to the contributors of the nests is not an accidental *lapsus calami* is shown further on, when we read that the visitor eating the soup will "at any rate have the satisfaction of knowing that he has before him a dish the principal ingredient of which was formed by the little swifts *and bats*[1] which inhabit the Gomanton Caves," &c., &c.

[1] The italics are mine.—E. L. L.

I too have visited caves from which large quantities of edible birds' nests were collected. I saw plenty of *bats*, but, unfortunately, none of their nests! The nests *I saw* were built by a "swiftlet" (*Collocalia*, Gray), and were more or less the *product of their own salivatory glands*. This fact was known as far back as 1781, over one hundred years ago!! The "*white nests*" are supplied entirely by the inspissated saliva of the bird, and are the first produced. These are taken, and sold for their weight in silver. The next made by the birds are mixed with rootlets, grasses, &c., and often show traces of blood, from the efforts of the birds to produce the saliva. These are esteemed second quality. The third nest is composed of extraneous substances cemented together and to the rock with a little saliva; these are generally left for the bird to breed in, and are usually destroyed at the end of the season to compel the birds to build fresh *white* ones after their powers are recruited by a year's rest and stimulated by the breeding "*storge*."

All this genus—the swiftlets (*Collocalia*)—wherever found, produce, in a greater or less degree, an amount of saliva which is used in building their nests and attaching them to the surfaces of rocks or the insides of hollow trees and leaves. The properties in this *saliva*—as in the *kava* of the Fijians and the *pepsine* of the calf—give it its value in the eyes of the Chinese. If it were simply a "fungoid growth" woven together, why is it not gathered from the limestone rock in its pure state?

British Consulate, September 17 E. L. LAYARD

THE PRIME MERIDIAN CONFERENCE

WE believe that the protocols of this Conference have not yet reached this country. In the meantime we are permitted to give the official statement of the resolutions.

FINAL ACT

The President of the United States of America, in pursuance of a special provision of Congress, having extended to the Governments of all nations in diplomatic relations with his own, an invitation to send Delegates to meet Delegates from the United States in the City of Washington on October 1, 1884, for the purpose of discussing, and, if possible, fixing upon a meridian proper to be employed as a common zero of longitude and standard of time-reckoning throughout the world, this International Meridian Conference did assemble at the time and place designated; and, after careful and patient discussion, has passed the following resolutions:—

I. "*Resolved*, That it is the opinion of this Conference that it is desirable to adopt a single prime meridian for all nations, in place of the multiplicity of initial meridians which now exist."

This resolution was unanimously adopted.

II. "*Resolved*, That the Conference proposes to the Governments here represented the adoption of the meridian passing through the centre of the transit instrument at the Observatory of Greenwich as the initial meridian for longitude."

The above resolution was adopted by the following vote:—

In the affirmative—

Austria-Hungary,	Mexico,
Chili,	Netherlands,
Colombia,	Paraguay,
Costa Rica,	Russia,
Germany,	Salvador,
Great Britain,	Spain,
Guatemala,	Sweden,
Hawaii,	Switzerland,
Italy,	Turkey,
Japan,	United States,
Liberia,	Venezuela.

In the negative—

San Domingo.

Abstaining from voting—

Brazil,	France.

Ayes, 22 ; noes, 1 ; abstaining, 2.

III. "*Resolved*, That from this meridian longitude shall be counted in two directions up to 180 degrees, east longitude being plus and west longitude minus."

This resolution was adopted by the following vote :—

In the affirmative—

Chili,	Liberia,
Colombia,	Mexico,
Costa Rica,	Paraguay,
Great Britain,	Russia,
Guatemala,	Salvador,
Hawaii,	United States,
Japan,	Venezuela.

In the negative—

Italy,	Sweden,
Netherlands,	Switzerland.
Spain,	

Abstaining from voting

Austria-Hungary,	Germany,
Brazil,	San Domingo,
France,	Turkey.

Ayes, 14 ; noes, 5 ; abstaining, 6.

IV. "*Resolved*, That the Conference proposes the adoption of a universal day for all purposes for which it may be found convenient, and which shall not interfere with the use of local or other standard time where desirable."

This resolution was adopted by the following vote :—

In the affirmative—

Austria-Hungary,	Mexico,
Brazil,	Netherlands,
Chili,	Paraguay,
Colombia,	Russia,
Costa Rica,	Salvador,
France,	Spain,
Great Britain,	Sweden,
Guatemala,	Switzerland,
Hawaii,	Turkey,
Italy,	United States,
Japan,	Venezuela.
Liberia,	

Abstaining from voting—

Germany,	San Domingo.

Ayes, 23 ; abstaining, 2.

V. "*Resolved*, That this universal day is to be a mean solar day ; is to begin for all the world at the moment of mean midnight of the initial meridian, coinciding with the beginning of the civil day and date of that meridian, and is to be counted from zero up to twenty-four hours.'"

This resolution was adopted by the following vote :—

In the affirmative—

Brazil,	Liberia,
Chili,	Mexico,
Colombia,	Paraguay,
Costa Rica,	Russia,
Great Britain,	Turkey,
Guatemala,	United States,
Hawaii,	Venezuela.
Japan,	

In the negative—

Austria-Hungary,	Spain.

Abstaining from voting—

France,	San Domingo,
Germany,	Sweden,
Italy,	Switzerland.
Netherlands,	

Ayes, 15 ; noes, 2 ; abstaining, 7.

VI. "*Resolved*, That the Conference expresses the hope that as soon as may be practicable the astronomical and nautical days will be arranged everywhere to begin at mean midnight."

This resolution was carried without division.

VII. "*Resolved*, That the Conference expresses the hope that the technical studies designed to regulate and extend the application of the decimal system to the division of angular space and of time shall be resumed, so as to permit the extension of this application to all cases in which it presents real advantages."

The motion was adopted by the following vote :—

In the affirmative—

Austria-Hungary,	Mexico,
Brazil,	Netherlands,
Chili,	Paraguay,
Colombia,	Russia,
Costa Rica,	San Domingo,
France,	Spain,
Great Britain,	Switzerland,
Hawaii,	Turkey,
Italy,	United States,
Japan,	Venezuela.
Liberia,	

Abstaining from voting—

Germany,	Sweden.
Guatemala,	

Ayes, 21 ; abstaining, 3.

Done at Washington, October 22, 1884.

C. R. P. RODGERS, Rear-Admiral U.S.N., *President*,
L. CRULS (Brazil), JANSSEN (France), R. STRACHEY (Great Britain) . . . } *Secretaries.*

"*Resolved*, That a copy of the resolutions passed by this Conference shall be communicated to the Government of the United States of America, at whose instance and within whose territory the Conference has been convened."

ON THE INTERFERENCE-CURVES KNOWN AS "OHM'S FRINGES"

PERHAPS I may be allowed to recall the attention of physicists to the above "strange and interesting phenomena," as they are rightly called by their discoverer, Prof. G. S. Ohm (see *Pogg. Annalen* for 1853, vol. xc. p. 327) ; partly for the purpose of indicating a simple method of observing them.

According to Prof. Ohm's directions two plates of equal thickness are to be cut from a uniaxial crystal, with parallel surfaces making an angle of 45° with the optic axis. One of these plates is to be placed on the other in such a position that the optic axes lie in the same plane but on opposite sides of the normal common to the two plates, with which they make, of course, equal angles of 45°. When this combination is held in a convergent beam of plane-polarised monochromatic light (*e.g.* yellow sodium light), numerous alternations of bright and dark elliptical bands are seen, most distinctly when the plane containing the optic axes makes an angle of 45° with the plane of polarisation of the light.

Of course a pair of "Savart's band" plates, when properly oriented, will answer for the above experiment ; but the peculiar double refraction of quartz causes more complicated but beautiful results.

Now, since in Iceland spar the optic axis makes an angle of very nearly 45° (strictly, 44° 36′) with the natural faces of the rhombohedron, all that is required is to obtain an even cleavage-plate of the spar, about 2 cm. × 1 cm. and about 2 mm. thick, to break it in half, to turn one of the pieces round in a plane parallel to its surfaces through an angle of 180° from its position when broken off, and to cement it on the other piece in this position with Canada balsam or dammar.

Then, on placing the combination in a polariscope (for instance, laying it on the eye-lens of a microscope with analyser just above it) the series of ellipses will be well seen. Sodium light, *e.g.* that from a Bunsen burner with a bead of sodium carbonate held in the flame, must be used.

Prof. Ohm refers to a paper by Langberg (which I have not been able to get a sight of) in which the occurrence and form of these bands were predicted from theory; so that the case resembles those of Airy's spirals and Hamilton's conical refraction.

A pair of plates with surfaces making an angle of 70° (or more) with the optic axis also show these ellipses; and perhaps more instructively, since with such plates it is easy to trace the origin of the bands in the coalescence of portions of the circular isochromatic bands of high order which surround the optic axis in each plate.

Those who have a pair of Savart's plates mounted so that one can rotate over the other, will find it most interesting and instructive to watch (in monochromatic light) the changes in form and character of the interference-bands as the azimuth of one of the plates is gradually altered.

Eton College H. G. MADAN

CONTINUOUS AUTOMATIC BRAKES

THE returns of the Railway Department of the Board of Trade serve as an excellent index to the defects in the management and working of the railway system in this country, the defects being brought to light during the investigations of the trivial casualties and disastrous accidents which take place, and inquired into by the experienced inspectors of the Board of Trade.

It is evident that by far the greater number of accidents seem to have been caused by the trains not being fitted with a really good brake, and in consequence being unable to stop quickly in cases of emergency. Some even have been caused by the brake itself failing to "go on" when required, caused either by some defect in the brake mechanism, or the design of the brake itself has been bad, giving the engine-driver a false sense of security, and leading the train with its living load into unnecessary danger.

It is a pity the railway companies do not pay more attention to the conditions laid down by the Board of Trade with regard to continuous brakes, stating the qualities the brake ought to possess, for it is evident the Board does not wish the adoption of any particular patentee's brake, but a brake which includes to the fullest extent the conditions laid down. It so happens that the Westinghouse automatic brake answers the conditions better than any other, and therefore the Board is anxious to see it in general use, not because an ex-inspector of the Board happens to be the chairman of the English Westinghouse Brake Company, as the secretary of one English railway seems to imagine, but because it is the best brake.

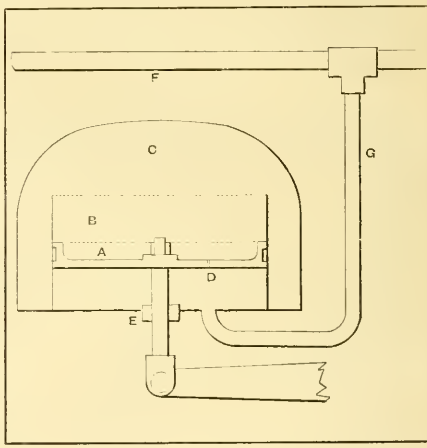
In an extract from the Board of Trade returns on continuous brakes for the half year ending June 30, published by the Vacuum Brake Company, we find the Westinghouse automatic credited with 397 faults for a mileage of 15,506,447.

We think it may be truly stated that the Westinghouse automatic has not had fair play with some of the companies having it partially in use, its failures having been carefully reported, while any failure of their own special brake, not having any serious consequences, has been looked over.

Take for instance the returns sent in by the Midland Company. Here the Westinghouse automatic has failed thirty-seven times for a mileage of 374,390, or one fault for every 10,118 miles, while the Midland automatic vacuum has six failures reported for a mileage of 5,245,573, or one fault for every 874,262 miles run. On the other hand we have the London, Brighton, and South Coast Railway using the Westinghouse automatic on the whole of their trains; they report seventy-four failures for a mileage of 3,122,510, or one fault for every 42,196 miles run.

Why should the Westinghouse automatic run four times as many miles per failure on the Brighton line than on the Midland? The reason is not far to seek; on the Brighton line the Westinghouse automatic is properly looked after, and kept in good repair, while on the Midland it has to stand back and give place to the vacuum automatic, the Company's brake.

The automatic vacuum brake in use on the Midland Railway has, as its name implies, the pressure of the atmosphere opposed to a partial vacuum for its motive



power, the vacuum being created by means of an ejector on the engine, connected to every vehicle on the train by means of a continuous pipe, having flexible pipes and couplings between the vehicles. To maintain the vacuum throughout the train against leakage, there is a small ejector continually in use on the engine.

Coupled to the continuous pipe on each vehicle is the automatic brake cylinder and reservoir peculiar to the Midland automatic brake, the piston being connected by means of levers and rods to the brake-blocks. The illustration gives a good idea of the general construction of the brake-cylinder and its connections, the arrangement being as follows:—The brake-cylinder B is placed inside the reservoir C, the piston A working air-tight in the cylinder; the piston-rod passing through the bottom of the cylinder by means of a gland, E, having a flexible packing ring. so arranged that when the piston is at the bottom of the cylinder it comes in contact with the packing ring, making an air-tight joint; but when the piston moves upwards, leaving the packing ring, air is able to pass through the gland into the lower part of the brake-cylinder. The continuous pipe F is connected by the branch pipe G to the lower part of the brake-cylinder.

Through the piston there is a small hole, D, called the leak-hole, this being one of the main features of the brake, the mode of action of which is as follows:—A vacuum is created in the continuous pipe by means of the ejector on the engine, the air being drawn from below the pistons in the brake-cylinder by the branch connections; the air in the reservoir C leaks through the leak hole D, and after a short time there is an equal vacuum above and below the pistons. The brake is now charged, and in its usual condition when the train is running, the vacuum being maintained against acccidental leakage by the continual use of the small ejector.

To apply the brake, air is admitted into the continuous pipe, destroying the partial vacuum, and, increasing the pressure below the pistons, causes them to rise, breaking at the same time the air-tight joint made by the piston against the packing ring, thereby admitting air *direct*, through the gland, into the lower part of the brake-cylinder, causing the application of the brakes to be nearly instantaneous. It will be observed that, directly the piston is forced up by the atmospheric pressure, the vacuum in the reservoir will gradually be destroyed by air passing through the leak-hole, in fact after less than two minutes it has leaked itself entirely off. It is also evident that it cannot be instantly charged, for the vacuum in the reservoir has to be created through the leak-hole.

It is stated by some that the Midland automatic vacuum answers all the Board of Trade conditions, and is therefore to be regarded as an effective serviceable automatic brake. On studying the reports in the returns, and the failures of this brake as reported in the technical papers, we see how absurd the claim to efficiency becomes. For example, the brake cannot be applied *quickly* several times in succession; when applied even once, the effective brake power has all vanished in two minutes, thus getting the doubtful name of the "two-minute leak-off brake." Again, suppose a train became divided from any cause, when ascending a heavy gradient, the brake should automatically apply itself, and *remain applied* until taken off by hand. What would the Midland automatic vacuum do under the above circumstances? Certainly the brake would apply itself, but in two minutes or less all the available brake power will have vanished, and, should the hand-brake in the rear van not prove powerful enough to hold the train on the bank, it will commence to run back.

Although the Midland Company have the automatic vacuum in general use, it is no criterion that the brake is satisfactory; we have only to add that the engines and tenders are fitted with an efficient steam brake, so that in entering stations, should the automatic vacuum fail, the steam brake is quite capable of stopping the train, only taking a little further distance to pull up in. At terminal stations sometimes this is very awkward, as the accident at the Liverpool Central Station, which happened some time ago, shows. Here the automatic vacuum brake failed, and the train ran into a brake-van standing by the stop-blocks, doing considerable damage. Reports of failures of the Midland automatic vacuum may be seen almost weekly in the "Railway Matters" column of the *Engineer*, and we give, as an example taken at random, one reported in the issue for October 17:—"As it is not very likely to be elsewhere recorded, it may be here mentioned that on the 10th inst. a twelve-coach Midland Scotch express ran clean through Bedford station before it was stopped, in consequence of the failure of the leak-off vacuum brake." Such failures are highly dangerous, and any brake with which they are likely to occur cannot be efficient, and therefore ought not to be trusted to stop trains at any important junction or station, and its use absolutely prohibited on approaching a terminal.

It may be interesting to have a short account of the Westinghouse automatic pressure brake, the worst fault of which, according to its opponents, is its efficiency in stopping trains should anything go wrong with the brake apparatus. The motive power of this brake is compressed air at a pressure of about 80 lbs. to 100 lbs., compressed by an ingeniously constructed steam-pump on the engine, and stored in a main reservoir under the foot-plate; throughout the train runs a pipe, connected between the vehicles by means of flexible hose pipes and couplings. On each vehicle, including the engine, is placed a small reservoir, a triple valve, and a brake cylinder, with a piston connected by levers and rods to the brake blocks. On the engine is placed the driver's brake-valve for working the brake. The whole system of this brake lies entirely in the construction and action of the triple valve. When the brake is in use, the train-pipe and small reservoirs are charged with compressed air, the air passing through the triple valve in its passage from the train-pipe to the small reservoirs. On the air-pressure being reduced, the triple valve opens a passage between the small reservoir and the brake-cylinder, thus allowing the compressed air stored to expand into the brake-cylinder, forcing out the piston, and applying the brake. To take the brake off, the converse happens: the pressure in the train-pipe is increased, the triple valve closing the passage between the small reservoir and the brake-cylinder, at the same time allowing the compressed air in the brake-cylinder to exhaust into the atmosphere, the small reservoir again being charged with compressed air from the train-pipe.

The triple valve consists of a small cylinder having a piston connected on the upper side to a small slide-valve working over two ports, arranged one about the other, the lower opening direct to the atmosphere, the upper connected by a pipe to the brake-cylinder. The slide-valve works in a small casing connected to the small reservoir; the triple valve is connected to the train-pipe by a pipe opening into the lower part of the cylinder in which the small piston works. When the piston is at the top of the cylinder it opens a connection between its lower and upper side, thus allowing compressed air to pass round the piston into the casing in which the slide-valve works, then into the small reservoir. When in this position, the slide-valve has closed both ports to the compressed air in the casing, the port leading to the brake-cylinder being open, through the valve, to the lower or exhaust port.

On charging the train-pipe with compressed air it will be observed that the piston in the triple valve will be forced up, thus filling the small reservoir and triple valve with compressed air, but *not* the brake-cylinder; also that the pressure of air on both sides of the piston in the triple valve will be equal; on reducing the air-pressure in the train-pipe by a few pounds, the piston will naturally be forced down, by the greater pressure on the upper side moving the slide-valve and allowing a quantity of the compressed air in the small reservoir to enter the port leading to the brake-cylinder, and apply the brake.

The air expanding into the brake-cylinder will cause its pressure to be reduced, and therefore balance the piston in the triple valve. It is evident therefore that any small reduction of pressure in the train-pipe will cause a corresponding application of the brake, a reduction of the pressure by 25 lbs. being sufficient to put the brake hard on and skid every wheel.

The function of the driver's brake-valve is to work the brake-apparatus by varying the pressure of the air in the train-pipe. In the first position of the handle which works the valve, called the charging position, air from the main reservoir is able to go direct to the train-pipe, to charge or release the brake. On moving the handle through an angle of a few degrees into the feed-position, the connection between the main reservoir and the train-pipe is closed, the compressed air having to pass through a pressure-reducing valve on its way to the train-pipe from the main reservoir to make up for any slight leakage which may occur.

It is important that the pressure of the air in the main

reservoir should always be about 15 lbs. above that in the train-pipe, so that when the brakes are being released by increasing the pressure in the train-pipe *direct* from the main reservoir, the triple valves are certain to act, on account of the extra 15 lbs. pressure in the train-pipe above the pressure in the small reservoirs.

On moving the handle of the driver's valve further in the same direction, or into the position for applying the brakes, all connection between the main reservoir and the train-pipe is cut off, at the same time that the train-pipe is put in connection with the atmosphere, through an exhaust port; by this means the pressure in the train-pipe can be reduced to any degree to apply the brake. All brake-cylinders on vehicles are fitted with a release-valve, so that, should the brake be applied when the engine is not attached, the air can be discharged from the brake-cylinder, through the release-valve, by pulling a wire attached to the valve.

All vehicles now fitted with this brake have cocks at each end of the train-pipe, so that, should any change have to be made in the train, the coupling or uncoupling of vehicles is easily accomplished without the brake automatically applying itself.

It is easy to see that this brake is automatic in its action, for should the train-pipe or flexible couplings be injured by accident, or the train part into two or more portions, the compressed air will escape from the train-pipe, and the brake will apply itself. In all guards' vans is placed a cock in connection with the train-pipe, so that, should the guard observe anything wrong with the train, or receive a signal from a passenger, he can instantaneously apply the brake by opening the cock and discharging the air from the train-pipe.

The Westinghouse automatic brake is at present the only one which really includes all the qualities in the Board of Trade requirements for continuous brakes, and perhaps it will not be out of place to state the requirements of the Board of Trade.

(1) The brakes to be efficient in stopping trains, instantaneous in their action, capable of being applied without difficulty by engine-drivers and guards.

(2) In cases of accident, to be instantaneously self-acting.

(3) The brakes to be put on and taken off (with facility) on the engine and every vehicle of a train.

(4) The brakes to be used in daily working.

(5) The material employed to be of a durable character, so as to be easily maintained and kept in order.

On looking through the Board of Trade returns on continuous brakes for the six months ending June 30, one sees that over two-thirds of the failures of the Westinghouse automatic are due to burst hose pipes alone, and therefore not failures of the brake itself, but of faulty inspection and bad material. We would like to hear of experiments being made with a stronger and more durable material, so as to resist the destructive action of the oil and tallow, of which such a large quantity is used on railways. Could this improvement be effected, we are convinced the number of miles run per failure would immediately vastly increase, leaving the automatic vacuum brake far behind. Of failures of the triple valve to act we find fifteen reports, causing a very trifling delay to the trains. The air-pump is reported with eleven failures, and the driver's brake-valve has no failures recorded against it. When we consider the enormous mileage of 15,506,447 miles run by trains fitted with the Westinghouse automatic for the six months ending June 30, we cannot help being astonished at the freedom from failure of the different parts, and the general efficiency of the apparatus.

Much has been written about the failure of the simple vacuum brake in the Penistone accident on the Manchester, Sheffield, and Lincolnshire Railway, the disaster being attributed by some to the brake failure alone. Certainly, had the train been fitted with the Westinghouse automatic, the brake power on each vehicle would have remained intact, no matter how many couplings broke: but at the same time the fact seems to have been overlooked that the train had no permanent way to run on, since the engine broke up the chairs as it advanced, and the question remains, How would the train have been affected, having nearly all the wheels locked by the brake, and running over sleepers alone? Perhaps the train would not have travelled so far before going over the embankment; but we think the disaster would have been equally serious, each vehicle becoming detached by the sudden application of the brake, the couplings breaking on account of the violent jerks in passing over the sleepers, the curve tending to throw the vehicles over the embankment. As an example of the life-saving qualities of an automatic brake in an accident, we think the Penistone disaster would have been a poor specimen.

The question of automatic *versus* simple brakes, both pressure and vacuum, is now fairly before the public, and the policy of the Board of Trade seems more apparent every day. It would not be wise on their part to enforce the adoption of any particular patent brake, for a better one may any day be discovered, but the Board may fairly insist that their conditions as to the qualities of any brake adopted by any Company should be complied with, and, if necessary, enforced by Act of Parliament.

THE GALVANOMETER OF D'ARSONVAL AND DEPREZ

GALVANOMETERS of innumerable kinds abound, and each form has some special merit which renders it useful for certain restricted services. The old astatic instrument of Nobili is still preferred by many to the more modern mirror galvanometer of Sir W. Thomson because it requires no lamp, and can be used without darkening the room. The tangent galvanometer still holds its own in the testing-room for simple tests; and the lineman's detector is still indispensable on the score of its portability. For commercial purposes, where strong currents and steady potentials have to be measured, the newer ampere-meters and volt-meters have displaced the older forms of instrument. But still there is no best galvanometer of universal adaptability, even the Siemens "universal" galvanometer being too clumsy to meet with general favour.

For the purposes of the private laboratory a galvanometer is desired which shall be sensitive, yet accurate in its indications, capable of being used for measuring currents of all kinds, weak and strong, and of measuring differences of potential from the thousandth of a volt to a thousand volts. It ought to be capable of being used in broad daylight; of being rapidly read off; and it ought also to be independent of external magnetic disturbances. The annoyances which arise from the last two causes when working with sensitive galvanometers are only too well known. The needle of the instrument once deflected continues to oscillate perhaps for half a minute, perhaps longer, causing vexatious delays, and when perhaps it has settled down at last to zero, some person in the next room moves a piece of iron—a poker, a penknife, or some other magnetic object—causing the zero of the instrument to change. An aperiodic dead-beat instrument, not subject to external magnetic forces, would be a boon indeed.

A galvanometer which, without being absolutely perfect, goes very near to fulfilling these desirable conditions has lately been put into the hands of electricians by M. Carpentier, of Paris, successor to the well-known Ruhmkorff. It is the invention of M. Marcel Deprez as modified and improved by Dr. d'Arsonval. The many novel features which it presents would of themselves justify its description in the pages of NATURE: and the general excellence

of its performance, of which the writer of these lines can personally testify, is already widely acknowledged.

The main peculiarity of the new instrument lies in the fact that, whereas in almost all galvanometers there is a fixed coil and a movable magnetic needle, in this galvanometer the coil is movable and the magnet—no longer a mere needle but a substantial compound horse-shoe of steel—is fixed. Fig. 1 represents the instrument itself. The steel magnet, made of three thin horse-shoes each magnetised as strongly as possible, is firmly fixed to a metal base, with its poles upwards. Between the poles hangs the coil, rectangular in form and extremely light, held in its place by a thin silver wire above and another thin silver wire below. This coil is made by winding on a rectangular core, which, after the strands have been cemented and bound together, is removed, leaving the wire only. It weighs only a few grains. To reinforce the magnetic field a small cylinder of soft iron, small enough to lie in the hollow of the suspended rectangular coil without touching it, is placed between the poles and is rigidly supported from behind. The coil is then free to turn in the very narrow space between the

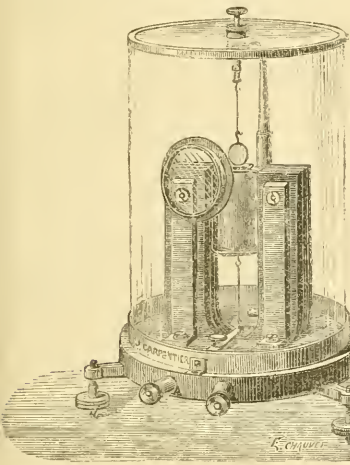


Fig. 1.

iron core and the external magnet-poles; and it need hardly be added that this contrivance produces a very intense magnetic field. The current is led in by one of the silver suspension-wires, and leaves the coil by the other. So far the arrangement precisely resembles that adopted in the well-known "siphon-recorder" of Sir W. Thomson, invented twenty years ago for the purpose of cable-signalling. A small mirror of 1 metre focus is affixed to the suspended coil; a brass spring at the bottom keeps the suspending wires adequately stretched; and a screw-head at the top of the instrument serves both to regulate the tension in the wires and to let the coil down, to a position of rest on the central iron cylinder, whenever the galvanometer is to be dismounted for removal to a distant place. The resistance of the coil is about 150 ohms in the ordinary pattern of instrument. As there is no suspended needle, no external magnetic forces affect the zero of the instrument; and, since the position of the coil is determined solely by the elasticity of the suspending wires and the magnetic action of the fixed magnet on the current in the coil, it can be used in any position, and is independent of the earth's magnetic field. It can even be placed quite near to a dynamo-machine. The intensity of the magnetic field in which the coil is situated is such that whenever the galvanometer-circuit is closed—even through a considerable resistance—the motion of the needle is dead-beat. It takes less than *one second* to come to rest at its final position of deflection, and when it returns to zero it does so with the most complete absence of oscillations. The spot of light on the scale never oscillates so much as 1 millimetre over the zero on releasing the galvanometer-key.

The optical arrangements adopted by M. Carpentier are shown in Fig. 2. The instrument is set with its three levelling screws in three V-grooves in a convenient bed-plate. Opposite it is set a semi-transparent scale of celluloid, 50 centimetres in length, graduated in millimetres. The light is provided by a single wax candle held in a holder like a carriage-candle, which also carries a paraboloidal mirror back. This candle is set so that its light falls upon a small adjustable plane mirror fixed to the back of the scale. This mirror reflects the ray upon the small mirror of the galvanometer, but as it passes beneath the scale it traverses a square aperture across which a thin wire is stretched vertically. To see the spot of light the observer stations himself in front of the scale, so as to see the light coming through the strip

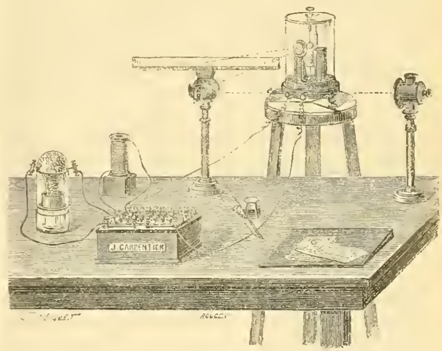

Fig. 2.

of celluloid. He sees a bright patch about 1 inch square having a single sharply-defined black line—the image of the aforesaid wire—down its middle. This patch of light and the central line are perfectly visible in broad daylight, but cannot be well seen by more than one observer at one time. The adjustment of the lamp and scale is a simple matter; and light from any lamp in the room—an overhead gas-light for example—may be used instead by turning the adjustable mirror to the proper angle.

When set up without any shunt, this galvanometer will show a deflection of 1 millimetre on the scale for about 1/100,000,000 of an ampere of current: but the sensitiveness differs in different instruments with the construction of the coil, the stiffness of the suspension, and the power of the magnets. Two instances of its application may be given.

The instrument can be applied as a volt-meter to measure the electromotive forces of cells in the manner indicated in Fig. 3. An ordinary reversing-key, K, is connected to the galvanometer, and an adjustable resistance (a Wheatstone rheostat with a thin wire having a range from 1 to 200 ohms is convenient) is interposed as a shunt, S. To calibrate the instrument a standard Daniell cell (E.M.F. = 1·07 volt) is placed at B in circuit with a resistance box. A resistance of 10,000 ohms is unplugged and a reading

is taken of the galvanometer, first to left, then to right, and the shunt-resistance is then adjusted until the scale reading is $53\frac{1}{2}$ millimetres on either side of zero, making a total of 107 millimetres. We then know that a deflection of 1 millimetre right or left will be produced by an electromotive force of 1/200 of a volt. The cell whose electromotive force is to be tested is then substituted at B in place of the standard cell, and readings taken right and left; these are added, and divided by 100, giving the E.M.F. of the cell directly in volts.

To measure currents the same calibration is made with a standard cell. In the circuit of the current to be measured is interposed a wire of some small but accurately-known resistance—for example, a standard 1 ohm, or, for stronger currents, a standard wire of 0·1 ohm. The two extremities of this coil are then connected to the key (Fig. 3), the 10,000-ohm coil being interposed as before. If the current to be measured is 1 ampere, it will, in passing through the standard 1 ohm, produc

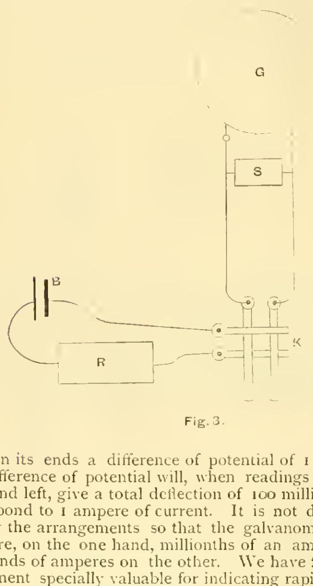

Fig. 3.

between its ends a difference of potential of 1 volt, and this difference of potential will, when readings are taken right and left, give a total deflection of 100 millimetres to correspond to 1 ampere of current. It is not difficult to modify the arrangements so that the galvanometer may measure, on the one hand, millionths of an ampere, and thousands of amperes on the other. We have found the instrument specially valuable for indicating rapid fluctuations of current in experiments on the induction of currents in armature coils when moved in a magnetic field. Its complete aperiodicity and the very small inertia, both mechanical and electrical, of its coil, render it most valuable for such work. The only defect—and that not a serious one—observed in three months of use, is a slight sub-permanent torsion on the suspending wires after taking a large deflection; but the method of taking double readings, first to right, then to left, eliminates any error that might arise from this cause.

THE BASALT-FIELDS OF NEW MEXICO

GEOLOGISTS interested in the history of the younger lava-floods, by which such vast areas both in the Old World and in the New have been deluged, will be glad to know that Capt. Dutton, of the United States Geological Survey, after a careful study of the modern volcanic phenomena of the Sandwich Islands, has undertaken the investigation of the basalt-territory lying in New Mexico, to the east and south of the area already so fully described by him in his Monographs on the Utah plateaux and the Cañon country. It was originally intended that he should have charge of the Survey of the Cascade Range. This arrangement was changed at the beginning of this last season. The Cascade ground was intrusted to his able assistant, Mr. Diller, while Capt. Dutton himself struck southward for a region in New Mexico, which he had long wished to study, from the light which he believed it would throw upon some of the later phases of volcanism in the Western Territories. I have received a long letter from him, written in his camp at the San Mateo Mountains, from which, with his permission, I send the following extract for publication in NATURE. ARCH. GEIKIE

Our wonderful Plateau Country we have known only in part, and the portion we have studied most is situated upon the western and northern side of the Colorado. Numerous geologists have hurried over the southern and south-eastern portion; but so rapidly have they been obliged to move in order to keep pace with the expeditions of which they were mere appendages that very little systematic knowledge could be gained. During the last two years our topographers have made some excellent maps of this region, and everything is ripe for the geologist.

I have described the western and southern portions of the Plateau Country as being very sharply defined in a geological as well as in a topographic sense. I think it will in great part prove to be equally well-defined in the south-eastern portions. Already it is clear to me that the Rio Grande River constitutes a portion of that boundary in this territory. Everywhere within range of my present field the strata characteristic of the Plateau Country rise gently from the Rio Grande to the westward. Cliffs, mesas, and terraces, carved buttes, and gorgeous colours are as typical of this region as they are of Utah and Northern Arizona. There is, however, more of the Cretaceous system preserved, and rocks of that age predominate, though the Trias and Permian are magnificently exposed. Indeed, the Vermilion Cliffs of Southern Utah have reappeared here in all their grandeur and glory, with but slight changes of detail.

But the features which are engaging my particular attention at this moment are the volcanic vestiges. This region has long been known under the mysterious name of *Malpais*—mysterious, however, only to those who have not read Humboldt's account of the *malpais* of Old Mexico. All the mesas, or platforms of sedimentary beds, within three or four miles of my camp, are sheeted over with basalt. The lava caps are not ordinarily more than fifty or a hundred feet thick; though just around me, in the very centre or focus of all, it becomes much thicker. In the valley-plains, also, are found many sheets of lava. But while the lavas upon the higher platforms and terraces are ancient, those in the valleys are very young. The centre of the activity has been (so far as concerns my present vicinity) the San Mateo Mountains. This name is synonymous with Mount Taylor, for the "Mountains" consist of a single volcanic pile (11,380 feet) carved into numerous spurs by magnificent gorges. It is a small Etna, built originally by outbreaks from its flanks as well as its summit. But the spread of the lavas from this centre is remarkable. To the north-north-east they reach out in unbroken continuity for forty-five miles, and for eighteen to thirty miles in the other directions. The lava beyond the immediate base of the mountain-cone is not thick. It forms a superficial sheet only on each mesa, or table, with a thickness varying from 50 to 200 feet.

The lava-capped strata have been cut into isolated mesas by subsequent erosion, and gaps of two or three miles sometimes separate one of these outliers from its parent mass.

This lava did not by any means come altogether from Mount Taylor itself, but from many vents scattered around its flanks, or situated miles away from it. These outlying vents are sufficiently preserved in many cases to admit of their complete identification, and they are very numerous. But one of the most charming and striking features consists in the numerous "necks" or "chimneys" which are left standing in the valley-plains beyond the farthest verge of the lava-capped mesas. Some of these are splendid objects. Newberry has depicted similar forms in the valley of the San Juan—a hundred miles or more to the north-west of here—in his admirable account of the observations made in his journey with Capt. Macomb's expedition. But these are even larger and finer, one being nearly two thousand feet high. What perfect testimony this is to the enormous erosion of the country! A child can read and comprehend it.

In the wide valley-plains which lie between the mesas are fresher fields of lava. Some look as if they could hardly be a century old; but my experience in the Hawaiian Islands has taught me that, in a dry country, a basalt-stream can preserve its freshness for many centuries. Still, it is clear enough that these eruptions occurred after hundreds, even thousands, of square miles of strata, overflowed by the older basalts, had been eroded away.

A striking fact in connection with these young basalts is the entire absence of all distinguishable traces of the vents from which they came. A few miles from here, in a broad valley, lies a basalt-field black as Erebus, and the whole circuit of it as accessible as a sheet of paper on a table, or a rug on the floor. There is no cone, no trace of fragmental ejecta, not a single feature in it to indicate the *locus* of eruption, except, however, the fact that the whole field, and the valley in which it lies, has a gentle declivity to the south-east, say forty feet per mile or so: and as the sheet follows the modern slope of the valley, it may be inferred that the vent is situated near the north-west end. There are many other fields of fresh lava, of which the above is sufficiently descriptive. One stream is nearly sixty miles long! Some of them, however, indicate unmistakably their sources in small depressed cones of very flat profiles. Great deluges of basalt have issued from them, flowing away for many miles, and spreading out five or six miles wide.

No fragmental ejecta (scoria, lapilli, &c.) have been found in connection with these young eruptions. But on Mount Taylor are numerous parasitic cinder-cones, of small or moderate dimensions, formed during the period of the eruption of the older basalts. The quantity of this fragmental material, however, is relatively very small.

The appearance of the young basalts is much like the rougher lava of Mauna Loa, called "aa" in the Hawaiian Islands. This is the typical *malpais* of this region. All the lava thus far seen is apparently basalt, though some of the older may prove to be andesitic when critically examined. There is little variety in it. It now appears that, all along the western, southern, and south-eastern rim of the Plateau Country is a marginal belt characterised by basaltic eruptions. I have identified two ages of eruption, both here and in South-West Utah. In the latter region I have associated these two periods of eruption with two periods of general upheaval of the plateaux. Whether the same will prove to be so here remains to be seen.

But it is getting dark, and I must close. We go to bed and get up with the chickens in this country.

C. E. DUTTON

NOTES

A MEETING of members of the University and others, to promote the objects of the Marine Biological Association, will be held at Cambridge on Saturday next, the 29th inst., in the Lecture-Room of Comparative Anatomy, the use of which for this purpose was granted to Prof. Newton by grace of the Senate on Thursday last. The Vice-Chancellor of the University (Dr. Ferrers, F.R.S., Master of Gonville and Caius College) has kindly undertaken to preside; and Prof. Moseley (the Chairman of the Council of the Association), Prof. Lankester (its Secretary), and Prof. Bell, of the British Museum and King's College, London, are expected to attend and set forth the aims and needs of their deserving body. The chair will be taken at three o'clock in the afternoon, and the proceedings (the details of which are being arranged by Mr. J. W. Clark, Superintendent of the Museum of Zoology and Comparative Anatomy, and Mr. Sedgwick, University Lecturer in Animal Morphology) are likely to be full of interest. The same evening the anniversary dinner of the Cambridge Philosophical Society will be given in the hall of Peterhouse, on the special invitation of the Master and Fellows of that ancient college, the newly-elected President of the Society, Prof. Foster, Sec. R.S., in the chair.

THE German Government has granted another sum of 7500*l.* for the scientific investigation of Central Africa, and 1900*l.* for the working out of the materials collected by German Polar expeditions.

THERE seems to be no end to the works of the highest value issued from the American *Nautical Almanac* Office. This week we have received a paper on "The Motion of Hyperion—a New Case in Celestial Mechanics," by Prof. Simon Newcomb, and another on "Lunar Inequalities due to the Ellipticity of the Earth," by Mr. G. W. Hill.

AT the first meeting of the new session of the Society of Arts held on November 19, Sir Frederick Abel made some feeling and pregnant remarks on the loss that not only the Society of Arts, but the whole scientific world, had sustained by the sudden and unexpected death of Sir William Siemens. In the course of his address Sir Frederick Abel said:—"It will be in the recollection of many whom I am addressing that, while Sir William Siemens was an ardent and successful labourer in the advancement of electric lighting, he also maintained the view that gas would continue to hold its own as the poor man's friend. The name of Siemens is associated with the origination of a great advance in the application of gas to the brilliant illumination of open spaces; but it must also be conceded that many streets and public places in London and the provinces bear evidence that even such simple modifications in the arrangement of old forms of gas-burners as have been introduced by Sugg and others have restored to gas some of its original prestige, and that, especially in towns where fogs are periodically prevalent, gas is now by no means wholly eclipsed by electricity as an open-air illuminant."

LAST week we announced the death of Dr. Wright of Cheltenham; to-day we have to make known that another of the lights of English geology has passed away. Mr. R. A. Godwin-Austen died at his residence, Shalford House, Guildford, on the morning of the 25th inst., after a long, but happily not a painful illness. He has for so many years lived retired in his country home that the younger generation of geologists has hardly known him personally. But his papers are classical in the literature of English geology, and long ago marked him out as one of the most philosophical of all the geological writers of this country.

MR. JAMES BUCKMAN, formerly one of the Professors at the Royal Agricultural College, Cirencester, and author of a number of geological papers, died at Bradford Abbas, Dorset, on the 23rd inst.

THE death is announced of Herr August Wilhelm Thienemann, the President of the German Society for the Protection of Birds, well-known in ornithological circles by his researches

and works. He died at Langenberg on the 5th inst., aged fifty-four years.

We regret to announce the death, at Paris, of M. Lartigue, aged fifty-four, a French electrician well known for his system of railway-signalling, which is largely in use on the French lines, and who had latterly held the post of General Director of the French Telephonic Company.

We regret to learn of the death, at the early age of thirty-four, of M. Henninger, one of the editors of *Science et Nature*. After a brilliant career as a medical student, he was appointed assistant to M. Wurtz in the chair of medical chemistry, as well as professor in l'École municipale de Chimie. He was the author of numerous articles in periodicals and encyclopædias, chiefly on chemistry.

The permanent Committee appointed by the International Ornithological Congress at Vienna for the purpose, among other tasks, of erecting ornithological stations of observation all over the globe, has addressed the Imperial Academy of Sciences in Vienna with the request that, so far as its sphere of action extends, it would seek out and appoint men, able and willing to undertake that office, to make regular observations, each within his own particular district, respecting the birds he finds there, their flight, incubation, mode of life, &c., and report them yearly (in the first quarter of the calendar year) to the Secretary of the Committee. The observations so collected will appear, each contribution being under the name and responsibility of the contributor, and will be scientifically digested and embodied by eminent experts. It is hoped that by these means many points hitherto dark in our knowledge of birds will be cleared up, and science generally be extended and enriched.

Admiral von Schleinitz has resigned the presidency of the Berlin Gesellschaft für Erdkunde, and has been replaced by Dr. W. Reiss. At the last meeting of this Society it was stated that there are now four Polar expeditions in preparation, of which one will start for the Antarctic regions. The African traveller, Dr. Aurel Schulz, has started on a journey across Africa from east to west, by way of the Zambesi River and the Victoria Falls. Lieut. Schulz, the leader of the German African expedition, reports from Cameroon that the joy of the German colonists there is most intense in consequence of recent political events.

The speeches delivered at the sittings of the Universal Prime Meridian Congress at Washington will be published *in extenso* in French, having been translated under the superintendence of M. Janssen, who was specially appointed by the Congress for that task.

The collections made by the Polar traveller, Capt. Jacobsen, by order of the Berlin Museum, on his American tour, are now on view at the Royal Ethnographical Museum at Berlin. That part of the collections which was obtained from Alaska territory, consists of some 4000 objects, collected among various Esquimaux tribes and among the Ingalik Indians living on the Yukon River. Most of the objects in question closely resemble those dating from the Stone Age, consisting principally of stone, bone, horn, shell, or wood.

The expedition of the German travellers, Dr. Clauss and Herr von den Steinen, who undertook to investigate the tributaries on the upper right bank of the Amazon and Xingu Rivers, starting from Paraguay and Cuyaba, have successfully accomplished this task, and safely arrived at Para at the end of October. The Brazilian Government, and especially Senhor Batovi, the Prefect of the province of Matto Grosso, have supported this scientific undertaking in a praiseworthy manner.

The Commission of the Centennial Exhibition for 1889 have already held several meetings with the object of determining upon a site for the Exhibition. As many as four places are competing for this honour, exclusive of the Bois de Boulogne, which was mentioned in connection with this matter some months ago.

The excellent "Monthly Reference-Lists," which are printed by Mr. W. E. Foster of the Providence Public Library, should be watched, says *Science*, by scientific men as well as by literary readers. The August number (vol. iv. No. 8) contains a handy index to articles on earthquakes—theories and observations—which was suggested by the shock of August 10, 1884. In judging of the list of memoirs and articles which are cited, the reader should remember that it is prepared for popular reading, and not as an index for the seismologist, nor even for the physicist. The second part of the same number is devoted to the early English explorations of America.

Telephonic service between Brussels and Antwerp was opened on October 20, the wires being used both for telegraphing and telephoning. The Belgian Government intends establishing telephonic connection between Brussels and Liége, Verviers, Mons, Ghent, Charleroi, and Louvain.

Among the awards given by the jurors at the National Italian Exhibition we notice a gold medal granted to Signor Ragona, Director of the Modena Observatory, for a complete set of astronomical, meteorological, and magnetical instruments designed by him and executed under his personal supervision.

In a recent number of the *Revue Scientifique* General Faidherbe draws the boundaries of the large section in the north-west of Africa in part already fallen, in part about to fall, under French control. In the beginning of April this year the French flag was floating from the fort of Bammakoo on the banks of the Niger, and on September 11 a French steamer had made a run down that river from Bammakoo to Koulikoro, bound for Timbuctoo, 300 miles lower down. Altogether, the French have at present the command of the Niger from Bourré to Boussa, some 700 leagues of water-course. From the North of Africa, again, a French railway runs from Arzen to Mécheria, and in a few years more will be continued to Imsalah. But Imsalah is already connected with Timbuctoo by the caravan routes which, under French protection, must become much more important. From Porto Novo on the Gulf of Guinea, moreover, the French cannot but push to Boussa on the Niger, and so complete their commercial route from the Mediterranean to the Gulf of Guinea.

We have received the Catalogue of the Natural History Collections of the Albany Museum, Grahamstown, Cape of Good Hope, and have much pleasure in observing how considerable the collection already is in specimens both native and foreign, especially birds. For the rest we can only join heartily in the hope expressed by the zealous curator in the preface, that the present inventory of natural history treasures in the young colony will stimulate able friends, at once of the colony and of natural science, to add to the stock and so promote the benign study of Nature in a part of the world not without its share of political troubles. We expect that the promised list of botanical specimens in the herbarium will do justice to the botany, at least, of the South of Africa.

On the eastern coast of Schleswig the experiments to establish oyster-beds are being actively pursued, under the direction of Prof. Möbius, who is an authority on the subject. Quantities of young American and Canadian oysters have been brought over, and are being "sown out" during favourable weather. The experiments made last year have, so far, not been attended with satisfactory results.

The organisation of the Pneumatic Postal Service will be completed on December 15 next for the whole of Paris. This great work, costing more than a million francs and involving over 60,000 metres' length of pipes, was inaugurated by M. de

Couchy, who, seventeen years ago, under the Empire, was Director of the French Telegraphs. The charge for carrying a letter to any place within the fortifications has been fixed at 3 *l*. The two extreme points in the service are about 11,000 metres apart, and the time required for the delivery of a letter to the remotest place in the most unfavourable circumstances, and including its conveyance from the nearest station, will be within one hour.

THE Scientific Exhibition at Paris, always held on the occasion of the grand *soirée* given by Admiral Mouchez, Director of the Paris Observatory, will this year be under the management of the French Electrical Society, and its exhibits will therefore be confined to objects relating to that branch of science.

PROF. MELL, Director of the Alabama Weather Service, announces, in *Science*, that through the liberality of the Chief Signal Officer, and of several railways, daily weather-signals, predicting changes of weather and temperature, will be displayed at over one hundred telegraph-stations in that State. The predictions will be received by the Director at an early hour every morning from the Signal Office in Washington, and then promptly distributed along the railways. By paying for the cost of the signal-flags (about six dollars), any town or telegraph-station will receive free telegraphic warning of the daily weather changes. Only about five minutes are required to set the flags. A similar system has been for some time in operation in Ohio and in part of Pennsylvania, and it will doubtless have further extension.

THE Commander-in-Chief of the French army in Tonquin has given orders to have a meteorological observatory erected in Haiphong, the chief port in the delta of the Red River, to serve as a basis for a network of meteorological stations with which it is intended to cover eventually the whole of Annam and Tonquin, and which will be in telegraphic communication with the observatory in Hong Kong.

THE series of illustrations of the methods and stages of instruction in handicraft and technical training contributed by the Austrian Government to the Health Exhibition is stated to have been purchased by the Japanese Government from the Technological Museum at Vienna. The Japanese authorities have also made numerous exchanges with the representatives of other countries exhibiting at South Kensington.

THE additions to the Zoological Society's Gardens during the past week include a Common Seal (*Phoca vitulina*) from British Seas, presented by Mr. James Wyat; two Barred Doves (*Geopelia striata*), three Eastern Turtle Doves (*Turtur meena*) from Java, presented by Mr. Emil Berg; a Green Monkey (*Cercopithecus callitrichus* ♂) from West Africa, deposited; a Red-throated Amazon (*Chrysotis collaria*) from Jamaica, a Red-tailed Amazon (*Chrysotis erythrura*) from Brazil, three Blue Snow Geese (*Chen cærulescens*) from Alaska, purchased; a Bernier's Ibis (*Ibis bernieri*) from Madagascar, received in exchange.

OUR ASTRONOMICAL COLUMN

THE ECLIPSE OF THUCYDIDES, B.C. 431, AUGUST 3.—There has been much discussion from time to time with reference to the solar eclipse recorded by Thucydides in the first year of the Peloponnesian war, and long identified as that which occurred on August 3, B.C. 431. We are told, "the sun was eclipsed after midday, and having assumed a crescent form, some of the stars having also appeared, it again became full-orbed." This eclipse was not total, as has been frequently stated, but narrowly annular. Dr. Hartwig in 1859 calculated the circumstances according to the solar and lunar tables of Hansen, and his results were published, with those applying to other eclipses mentioned by Thucydides, in No. 1203 of *Astronomische Nachrichten*. The greatest phase, by his calculations, falls at 5h. 9m. mean time at Athens, and the magnitude of the eclipse is 0·75, rather small, it will be considered, for stars to have been brought into view. But, when all the conditions of the case are borne in mind, it would appear quite possible, to speak within bounds, that Hansen's longitude of the moon may require at that epoch a correction which would suffice, with the rapid descent of the central line in latitude, to cause a great eclipse at Athens, leaving the sun of crescent form, as Thucydides reports, but with the crescent very narrow. In such a climate bright planets and stars might well have been discerned. Venus was westward at an altitude of some 35°, Mars would be near the western horizon, Jupiter had set, while Saturn was near the meridian at an altitude of something like 45°. Of the stars, Spica, Arcturus, Antares, and Vega were in favourable positions for observation.

Sir George Airy informed the writer of these lines some years since that, on the occasion of the partial eclipse of September 7, 1820, he "saw one or two stars" at Cambridge. On calculating the circumstances of the eclipse for that place, it appears the magnitude was 0·88. This is an interesting case in point.

WOLF'S COMET.—A few week's since it was remarked in this column that, according to the first elliptical orbit calculated by Prof. Krueger, this comet would approach very near to the orbit of Jupiter in about 209° heliocentric longitude, and great perturbation was possible early in the year 1875, so that the comet might not have been moving long in its present track. On this subject Prof. Krueger, who has recalculated the elements of the comet's orbit from a much wider extent of observation, expresses himself as follows in No. 2629 of the *Astronomische Nachrichten*:—"In Nr. 782 der NATURE (1884, October 23) ist hierauf bereits aufmerksam gemacht worden; ich hielt indessen damals die ersten Elemente für viel ungenauer, als sie wirklich waren, und glaubte, dass Erörterungen dieser Art noch etwas aufzuschieben seien. Die nachfolgende Rechnung bestätigt indessen die in der NATURE ausgesprochene Vermuthung in überraschender Weise." In fact, Prof. Krueger finds by his new orbit that on May 28, 1875, the comet's distance from Jupiter was less than 0·1 of the earth's mean distance from the sun, and hence it is probable that before the spring of this year the comet may have been describing a very different orbit to that in which it now moves. This, as was before remarked, will form an interesting subject of investigation, when definitive elements have been deduced from a combination of all the observations of the present appearance.

In Prof. Krueger's last orbit, founded on observations to November 7, the period of revolution is 2466·06 days, according to which the comet would have been in perihelion about February 16, 1878, in R.A. 23h. 58m., Decl. + 2°, distant from the earth 2·32, and under such circumstances not likely to have been seen. We subjoin other elements of the orbit:—

Semi-axis major ...	3·5722	Perihelion distance ...	1·5719
,, minor ...	2·9596	Aphelion ,, ..	5·5725
Semi-parameter ...	2·4521	Excentricity	0·559966

MINIMA OF ALGOL.—The following are approximate geocentric Greenwich times of minima of Algol, calculated from elements upon which the later observations of Schmidt have been brought to bear:—

THE WAVE THEORY OF LIGHT[1]

THE subject upon which I am to speak to you this evening is happily for me not new in Philadelphia. The beautiful lectures on light which were given several years ago by President Morton, of the Stevens' Institute, and the succession of lectures on the same subject so admirably illustrated by Prof. Tyndall, which many now present have heard, have fully prepared you for anything I can tell you this evening in respect to the wave theory of light.

It is indeed my humble part to bring before you some mathematical and dynamical details of this great theory. I cannot have the pleasure of illustrating them to you by anything compar-

[1] A Lecture delivered at the Academy of Music, Philadelphia, under the auspices of the Franklin Institute, September 29, 1884, by Sir William Thomson, F.R.S., LL.D.

able with the splendid and instructive experiments which many of you have already seen. It is satisfactory to me to know that so many of you, now present, are so thoroughly prepared to understand anything I can say, that those who have seen the experiments will not feel their absence at this time. At the same time I wish to make them intelligible to those who have not had the advantages to be gained by a systematic course of lectures. I must say in the first place, without further preface, as time is short and the subject is long, simply that sound and light are both due to vibrations propagated in the manner of waves; and I shall endeavour in the first place to define the manner of propagation and mode of motion that constitute those two subjects of our senses, the sense of sound and the sense of light.

Each is due to vibrations. The vibrations of light differ widely from the vibrations of sound. Something that I can tell you more easily than anything in the way of dynamics or mathematics respecting the two classes of vibrations is, that there is a great difference in the frequency of the vibrations of light when compared with the frequency of the vibrations of sound. The term "frequency" applied to vibrations is a convenient term, applied by Lord Rayleigh in his book on sound to a definite number of full vibrations of a vibrating body per unit of time. Consider, then, in respect to sound, the frequency of the vibrations of notes, which you all know in music represented by letters, and by the syllables for singing, the do, re, mi, etc. The notes of the modern scale correspond to different frequencies of vibrations. A certain note and the octave above it correspond to a certain number of vibrations per second and double that number.

I may explain in the first place conveniently the note called "C"; I mean the middle "C"; I believe it is the C of the tenor voice, that most nearly approaches the tones used in speaking. That note corresponds to two hundred and fifty-six full vibrations per second, two hundred and fifty-six times to and fro per second of time.

Think of one vibration per second of time. The seconds pendulum of the clock performs one vibration in two seconds, or a half vibration in one direction per second. Take a ten-inch pendulum of a drawing-room clock, which vibrates twice as fast as the pendulum of an ordinary eight-day clock, and it gives a vibration of one per second, a full period of one per second to and fro. Now think of three vibrations per second. I can move my hand three times per second easily, and by a violent effort I can move it to and fro five times per second. With four times as great force, if I could apply it, I could move it twice five times per second.

Let us think, then, of an exceedingly muscular arm that would cause it to vibrate ten times per second, that is ten times to the left and ten times to the right. Think of twice ten times, that is, twenty times per second, which would require four times as much force; three times ten, or thirty times a second, would require nine times as much force. If a person were nine times as strong as the most muscular arm can be, he could vibrate his hand to and fro thirty times per second, and without any other musical instrument could make a musical note by the movement of his hand which would correspond to one of the pedal notes of an organ.

If you want to know the length of a pedal pipe, you can calculate it in this way. There are some numbers you must remember, and one of them is this. You, in this country, are subjected to the British insularity in weights and measures; you use the foot and inch and yard. I am obliged to use that system, but I apologise to you for doing so, because it is so inconvenient, and I hope all Americans will do everything in their power to introduce the French metrical system. I hope the evil action performed by an English Minister, whose name I need not mention, because I do not wish to throw obloquy on any one, may be remedied. He abrogated a useful rule, which for a short time was followed, and which I hope will soon be again enjoined, that the French metrical system be taught in all our national schools. I do not know how it is in America. The school system seems to be very admirable, and I hope the teaching of the metrical system will not be let slip in the American schools any more than the use of the globes.

I say this seriously. I do not think any one knows how seriously I speak of it. I look upon our English system as a wickedly brain-destroying piece of bondage under which we suffer. The reason why we continue to use it is the imaginary difficulty of making a change, and nothing else; but I do not think in America that any such difficulty should stand in the way of adopting so splendidly useful a reform.

I know the velocity of sound in feet per second. If I remember rightly, it is 1089 feet per second in dry air at the freezing-point, and 1115 feet per second in air of what we call moderate temperature, 59° or 60°—(I do not know whether that temperature is ever attained in Philadelphia or not; I have had no experience of it, but people tell me it is sometimes 59° or 60° in Philadelphia, and I believe them)—in round numbers let us call it 1000 feet per second. Sometimes we call it a thousand musical feet per second, it saves trouble in calculating the length of organ pipes; the time of vibration in an organ pipe is the time it takes a vibration to run from one end to the other and back. In an organ pipe 500 feet long the period would be one per second; in an organ pipe ten feet long, the period would be fifty per second; in an organ pipe twenty feet long, the period would be twenty-five per second at the same rate. Thus twenty-five per second, and fifty per second of frequencies, corresponds to the periods of organ pipes of twenty feet and ten feet.

The period of vibration of an organ pipe, open at both ends, is approximately the time it takes sound to travel from one end to the other and back. You remember that the velocity in dry air in a pipe ten feet long is a little more than fifty periods per second; going up to 256 periods per second, the vibrations correspond to those of a pipe two feet long. Let us take 512 periods per second; that corresponds to a pipe about a foot long. In a flute, open at both ends, the holes are so arranged that the length of the sound-wave is about one foot, for one of the chief "open notes." Higher musical notes correspond to greater and greater frequency of vibration, viz., 1000, 2000, 4000 vibrations per second; 4000 vibrations per second correspond to a piccolo flute of exceedingly small length; it would be but one and a half inches long. Think of a note from a little dog-call, or other whistle, one and a half inches long, open at both ends, or from a little key having a tube three-quarters of an inch long, closed at one end; you will then have 4000 vibrations per second.

A wave length of sound is the distance traversed in the period of vibration. I will illustrate what the vibrations of sound are by this condensation travelling along our picture on the screen. Alternate condensations and rarefactions of the air are made continuously by a sounding body. When I pass my hand vigorously in one direction, the air before it becomes dense, and the air on the other side becomes rarefied. When I move it in the other direction, these things become reversed; there is a spreading out of condensation from the place where my hand moves in one direction and then in the reverse. Each condensation is succeeded by a rarefaction. Rarefaction succeeds condensation at an interval of one-half what we call "wave lengths." Condensation succeeds condensation at the full interval of what we call wave lengths.

We have here these luminous particles on this scale,[1] representing portions of the air close together, dense; a little higher up, portions of air less dense. I now slowly turn the handle of the apparatus in the lantern, and you will see the luminous sectors showing condensation travelling slowly upwards on the screen; now you have another condensation; making one wave length.

This picture or chart represents a wave length of four feet. It represents a wave of sound four feet long. The fourth part of a thousand is 250. What we see now of the actual scale represents the lower note C of the tenor voice. The air from the mouth of a singer is alternately condensed and rarefied just as you see here.

But that process shoots forward at the rate of one thousand feet per second; the exact period of the motion is 256 vibrations per second for the actual case before you. Follow one particle of the air forming part of a sound wave, as represented by these moving spots of light on the screen; now it goes down, then another portion goes down rapidly; now it stops going down; now it begins to go up; now it goes down and up again.

As the maximum of condensation is approached, it is going up with diminishing maximum velocity. The maximum of rarefaction has now reached it, and the particle stops going up and begins to move down. When it is of mean density the particles are moving with maximum velocity, one way or the other. You can easily follow these motions, and you will see that each particle moves to and fro, and the thing that we call *condensation* travels along.

[1] Alluding to a moving diagram of wave motion of sound produced by a working slide for lantern projection.

I shall show the distinction between these vibrations and the vibrations of light. Here is the fixed appearance of the particles when displaced but not in motion. You can imagine particles of something, the thing whose motion constitutes light. This thing we call the luminiferous ether. That is the only substance we are confident of in dynamics. One thing we are sure of, and that is the reality and substantiality of the luminiferous ether. This instrument is merely a method of giving motion to a diagram designed for the purpose of illustrating wave motion of light. I will show you the same thing in a fixed diagram, but this arrangement shows the mode of motion.

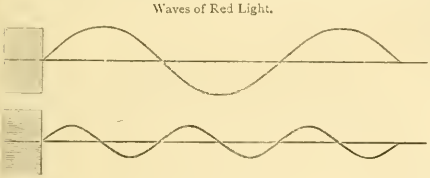
Now follow the motion of each particle. This represents a particle of the luminiferous ether, moving at the greatest speed when it is at the middle position.

You see the two modes of vibration,[1] sound and light now moving together,—the travelling of the wave of condensation and rarefaction, and the travelling of the wave of transverse displacement. Note the direction of propagation. Here it is from your left to your right, as you look at it. Look at the motion when made faster. We have now the direction reversed. The propagation of the wave is from right to left, again the propagation of the wave is from left to right; each particle moves perpendicularly to the line of propagation.

I have given you an illustration of the vibration of sound waves, but I must tell you that the movement illustrating the condensation and rarefaction represented in that moving diagram are necessarily very much exaggerated, to let the motion be perceptible, whereas the greatest condensation in actual sound motion is not more than one or two per cent. or a small fraction of a per cent. Except that the amount of condensation was exaggerated in the diagram for sound, you have a correct representation of what actually takes place in the low note C.

On the other hand, in the moving diagram representing light waves what had we? We had a great exaggeration of the inclination of the line of particles. You must first imagine a line of particles in a straight line, and then you must imagine them disturbed in a wave curve, the shape of the curve corresponding to the disturbance. Having seen what the propagation of the wave is, look at this diagram and then look at that one. This, in light, corresponds to the different sounds I spoke of at first. The wave length of light is the distance from crest to crest of the wave, or from hollow to hollow. I speak of crests and hollows, because we have a diagram of ups and downs as the diagram is placed.

Waves of Red Light.



Waves of Violet Light.

Here, then, you have a wave length.[2] In this lower diagram you have the wave length of violet light. It is but one-half the length of the upper wave of red light; the period of vibration is but half as long. Now, on an enormous scale, exaggerated not only as to slope, but immensely magnified as to wave length, we have an illustration of the waves of light. The drawing marked "red" corresponds to red light, and this lower diagram corresponds to violet light. The upper curve really corresponds to something a little below the red ray of light in the spectrum, and the lower curve to something beyond the violet light. The variation in length between the most extreme rays is in the proportion of four and a half of red to eight of the violet, instead of four and eight; the red waves are nearly as one to two of the violet.

To make a comparison between the number of vibrations for each wave of sound and the number of vibrations constituting light waves, I may say that 30 vibrations per second is about the smallest number which will produce a musical sound; 50 per second gives one of the grave pedal notes of an organ, 100 or 200 per second give the low notes of the bass voice, higher notes with 250 per second, 300 per second, 1000, 4000, up to 8000 per second give about the shrillest notes audible to the human ear.

Instead of the numbers, which we have, say in the most commonly used part of the musical scale, *i.e.* from 200 or 300 to 600 or 700 per second, we have millions and millions of vibrations per second in light waves; that is to say, 400 million million per second, instead of 400 per second. That number of vibrations is performed when we have red light produced.

An exhibition of red light travelling through space from the remotest star is due to the propagation by waves or vibrations, in which each individual particle of the transmitting medium vibrates to and fro 400 million million times in a second.

Some people say they cannot understand a million million. Those people cannot understand that twice two makes four. That is the way I put it to people who talk to me about the incomprehensibility of such large numbers. I say *finitude* is incomprehensible, the infinite in the universe *is* comprehensible. Now apply a little logic to this. Is the negation of infinitude incomprehensible? What would you think of a universe in which you could travel one, ten, or a thousand miles, or even to California, and then find it come to an end? Can you suppose an end of matter, or an end of space? The idea is incomprehensible. Even if you were to go millions and millions of miles the idea of coming to an end is incomprehensible.

You can understand one thousand per second as easily as you can understand one per second. You can go from one to ten, and ten times ten, and then to a thousand without taxing your understanding, and then you can go on to a thousand million and a million million. You can all understand it.

Now 400 million million vibrations per second is the kind of thing that exists as a factor in the illumination by red light. Violet light, after what we have seen and have illustrated by that curve, I need not tell you corresponds to vibrations of 800 million million per second. There are recognisable qualities of light caused by vibrations of much greater frequency and much less frequency than this. You may imagine vibrations having about twice the frequency of violet light and one-fifteenth the frequency of red light and still you do not pass the limit of the range of continuous phenomena only a part of which constitutes *visible* light.

Everybody knows the "photographer's light" and has heard of *invisible* light producing visible effects upon the chemically prepared plate in the camera. Speaking in round numbers, I may say that, in going up to about twice the frequency I have mentioned for violet light, you have gone to the extreme end of the range of known light of the highest rates of vibration; I mean to say that you have reached the greatest frequency that has yet been observed.

When you go below visible red light what have you? We have something we do not see with the eye, something that the ordinary photographer does not bring out on his photographically sensitive plates. It is light, but we do not see it. It is something so closely continuous with light visible, that we may define it by the name of invisible light. It is commonly called radiant heat; invisible radiant heat. Perhaps, in this thorny path of logic, with hard words flying in our faces, the least troublesome way of speaking of it is to call it radiant heat. The heat effect you experience when you go near a bright, hot coal fire, or a hot steam boiler; or when you go near, but not over, a set of hot-water pipes used for heating a house; the thing we perceive in our face and hands when we go near a boiling pot and hold the hand on a level with it, is radiant heat; the heat of the hands and face caused by a hot fire, or a hot kettle when held under the kettle, is also radiant heat.

You might readily make the experiment with an earthen teapot; it radiates heat better than polished silver. Hold your hands below, and you perceive a sense of heat; above the teapot you get more heat; either way you perceive heat. If held over the teapot you readily understand that there is a little current of air rising. If you put your hand under the teapot you get cold air; the upper side of your hand is heated by radiation, while the lower side is fanned and is actually cooled by virtue of the heated kettle above it.

That perception by the sense of heat, is the perception of something actually continuous with light. We have knowledge of rays of radiant heat perceptible down to (in round numbers) about four times the wave length, or one-fourth the period of visible, or red light. Let us take red light at 400 million

[1] Showing two moving diagrams, simultaneously, on the screen, one depicting a wave motion of light, the other a sound vibration.

[2] Exhibiting a large drawing, or chart, representing a red and a violet wave of light.

million vibrations per second; then the lowest radiant heat, as yet investigated, is about 100 million million per second in the way of frequency of vibration.

I had hoped to be able to give you a lower figure. Prof. Langley has made splendid experiments on the top of Mount Whitney, at the height of 15,000 feet above the sea-level, with his "bolometer," and has made actual measurements of the wave lengths of radiant heat down to exceedingly low figures. I will read you one of the figures; I have not got it by heart yet, because I am expecting more from him.[1] I learned a year and a half ago that the lowest radiant heat observed by the diffraction method of Prof. Langley corresponded to 28/100,000ths of a centimetre for wave length, twenty-eight as compared with red light, which is 7·3; or nearly fourfold. Thus wave lengths of four times the amplitude, or one-fourth the frequency per second of red light have been experimented on by Prof. Langley, and recognised as radiant heat.

Photographic, or actinic light, as far as our knowledge extends at present, takes us to a little less than one-half the wave length of violet light. You will thus see that while our acquaintance with wave motion below the red extends down to one-quarter of the slowest rate which affects the eye, our knowledge of vibrations at the other end of the scale only comprehends those having twice the frequency of violet light. In round numbers we have four octaves of light, corresponding to four octaves of sound in music. In music the octave has a range to a note of double frequency. In light we have one octave of visible light, one octave above the visible range, and two octaves below the visible range. We have 100 per second, 200 per second, 400 per second (million million understood) for invisible radiant heat, 800 per second for visible light, and 1600 per second for invisible light.

One thing in common to the whole is the heat effect. It is extremely small in moonlight, so small that nobody until recently knew there was any heat in the moon's rays. Herschel thought it was perceptible in our atmosphere by noticing that it dissolved away very light clouds, an effect which seemed to show in full moonlight more than when we have less than full moon. Herschel, however, pointed this out as doubtful; but now, instead of its being a doubtful question, we have Prof. Langley giving as a fact that the light from the moon drives the indicator of his sensitive instrument clear across the scale, and with a comparatively prodigious heating effect!

I must tell you that if any of you want to experiment with the heat of moonlight you must compare the heat with whatever comes within the influence of the moon's rays only. This is a very necessary precaution; if, for instance, you should take your bolometer or other heat detector from a comparatively warm room into the night air, you would obtain an indication of a fall in temperature owing to this change. You must be sure that your apparatus is in thermal equilibrium with the surrounding air, then take your burning-glass, and first point it to the moon, and then to space in the sky beside the moon; you thus get a differential measurement, in which you compare the radiation of the moon with the radiation of the sky. You will then see that the moon has a distinctly heating effect.

(*To be continued.*)

[1] Since my lecture I have heard from Prof. Langley that he has measured the refrangibility by a rock-salt prism, and inferred the wave length of heat rays from a "Leslie cube" (a metal vessel of hot water radiating from a blackened side). The greatest wave length he has thus found is one-thousandth of a centimetre, which is seventeen times that of sodium light. The corresponding period is about thirty million million to the second.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Professorship of Political Economy will be filled up on Dec. 13. The Higher Local Examinations were held last June at 21 centres, and attended by 960 candidates (chiefly women), a decrease of 27. In Arithmetic the work of most of the candidates was by no means good. Euclid's propositions were well and neatly written out. In some cases attempts were made to improve upon Euclid, but usually with disastrous results. The book-work of Geometrical Conics was fairly done by the few who attempted it, but only one rider out of four was solved by any candidate. Only a few candidates tried Analytical Geometry, and they nearly all did badly. Some very intelligent work was sent up in Algebra and Trigonometry. In Statics and Dynamics the majority of candidates had made but little way. The attempts at Astronomy were few and generally slight. Altogether, in Group C (Mathematics), there were only 140 candidates, of whom 41 failed, 70 obtained a third class, and only 12 attained a first class.

In Political Economy many of the answers were vague and indefinite. In Logic the simpler questions were well answered, and Mill's inductive methods were understood. Of 45 candidates, however, only 2 gained a first class.

In Group E (Natural Science), out of 62 candidates 25 failed, while 5 obtained a first class. In Elementary Chemistry and Physics the answers were mostly unsatisfactory; Elementary Biology was much better done. Very few candidates seemed to connect the definitions of Chemistry with the facts.

In Physiology and Zoology marked improvement was shown in the answers. The principal fault was still the want of personal acquaintance with phenomena that might be easily observed. In Botany the descriptions of plants were fairly well done, and the questions on Vegetable Physiology were attempted with some success by several candidates. No candidate, however, gave a good description of the germination of a seed.

In Physical Geography and Geology the answers were, on the whole, very good, and remarkably free from errors. The one common failing was the absence of good diagrams.

Mr. James Sully, M.A. Lond., has been appointed a member of the Board of Electors to the Professorship of Mental Philosophy and Logic, in place of the late Dr. Todhunter.

Dr. Donald MacAlister has been appointed by the Senate to be an Examiner in Medicine.

MANCHESTER.—At a meeting of the Council of the Victoria University, Owens College, on Friday, November 21, Mr. J. H. Fowler, B.A. (Oxon.) was elected, on the recommendation of the Senate, to a Berkeley Research Fellowship in Zoology. The Platt Physiological Scholarship, which is also for the encouragement of original research, has been awarded to Mr. C. F. Marshall, B.Sc. (Vict.).

SCIENTIFIC SERIALS

Journal of the Anthropological Institute of Great Britain and Ireland, November 1884.—The ethnology of Egyptian Soudan, a timely and important paper, by Prof. A. H. Keane.—Additional observations on the osteology of the natives of the Andaman Islands, by Prof. Flower.—The Kubus, a small tribe in Central Sumatra, by Mr. Forbes.—Notes on prehistoric remains in Antiparos, by Mr. Theodore Bent.—The Deme and the Horde, by Messrs. Howitt and Fison; an attempt to show a resemblance between the general organisation and usages of the Attic tribes and those of the Australian aborigines.—African symbolic messages, by the Rev. C. Gollmer, describing the method in which natives of the Yoruba country send messages to absent friends by means of shells, feathers, corn, stone, coal, sticks, &c.—On the size of teeth as a character of race, by Prof. Flower.—A Hindu prophetess, by Mr. Walhouse.—On certain less familiar forms of Palæolithic flint implements from the gravel at Reading, by Mr. Shrubsole.

THE *American Journal of Science* for November contains:—Mr. Asa Gray's paper on the characteristics of the North American flora, read before the Biological Section of the British Association at the Montreal meeting; also columbite in the Black Hills of Dakota, by Mr. Blake; spectro-photometric study of pigments, by Mr. Nichols; criticism of Becker's theory of faulting, by Mr. Ross Bourne; the difference between sea and continental climate with regard to vegetation, by Mr. Buysman; chemical affinity, by Mr. J. W. Langley; the relation between the electromotive force of a Daniell cell and the strength of the zinc sulphate solution, by Mr. Carhart; a notice of the remarkable marine fauna occupying the outer banks of the southern coast of New England, by Mr. Verrill; and a note by Mr. J. D. Dana, on the Costlandt and Stray Point hornblendic and augitic rocks.

Rivista Scientifico-Industriale, October 30.—On the origin of atmospheric electricity, of thunder-storms and volcanic eruptions (continued), by Prof. Giovanni Luvini.—Note on a simple method for determining the velocity of a railway train, by Prof. Steiner.—Note on Bauer's new radiometer, by the Editor.—On the vitality of insects in oxygen, hydrogen, carbonic acid, and prussic acid, by the Editor.

SOCIETIES AND ACADEMIES

London

Anthropological Institute, November 11.—Prof. Flower, F.R.S., President, in the chair.—The election of Horatio Hale, D. H. Talbot, Dr. F. A. Colby, and Mrs. E. A. Smith was announced.—Mr. Francis Galton described the object, method, and appliances of the late Anthropometric Laboratory at the International Health Exhibition, reserving the statistical results, which were not yet fully worked out, for another occasion. He established it to show with how little expense an elaborate course of measurements might be made, and how popular such a system of measurements would be. The result was that 9344 persons passed through the laboratory, each of them being measured in seventeen distinct particulars for the sum of 3*d.*, in a compartment only 6 feet wide and 36 feet long. The popularity of the laboratory was so great that its door was besieged by far more applicants than could be admitted, and many persons made repeated attempts and waited long for their turn, but at last gave up their attempts as hopeless. So many applications have been made abroad and at home for duplicates of the instrumental outfit that it was advisable that any suggested improvements in them should be considered before they became established in use. The present paper was to invite discussion. An identical set of instruments to those used at the Exhibition have been set up by Mr. Gammage, optical instrument maker, at 172, Brompton Road, assisted by Mr. Williams, who, between them, conducted all the measurements at the Healtheries; they make a moderate charge for measuring and keeping a register of the results.—Mr. H. O. Forbes read a paper on the people of the island of Buru.

Edinburgh

Royal Physical Society, November 19.—Ramsay H. Traquair, M.D., F.R.SS.L. and E., President, in the chair.—The President delivered the opening address, in which, after referring to the loss which the Society had sustained in the death of Dr. J. A. Smith, for many years its secretary, and subsequently one of its presidents, he called attention to the proceedings of last session as showing that the prosperity of the Society appeared not only in the increase of membership and ingathering of fees, but in scientific work accomplished.—Dr. Traquair then proceeded to discuss the subject of "Biological Nomenclature." Having shown the necessity for a nomenclature intelligible to all scientific men as distinguished from the common names of plants and animals, which varied in different countries, he referred to the introduction by Linnæus of the binomial system, under which each form received a generic and a specific name, and to the action taken by the British Association in 1842, and again in 1865, with the view of securing uniformity. Their rules and recommendations had, he said, worked well for the benefit of science, but they had not been in every particular followed by naturalists abroad, while even in this country there were often heard ominous notes of dissent as to their sufficiency for the wants of the science of the present day. They must, however, form the basis for all subsequent attempts to rectify the subject. Proceeding to discuss those rules, he urged the necessity of strict adherence to priority, and said he agreed with the rule that publication should mean the insertion of the description in a printed book, with the addition that such book might be had on sale. He also expressed concurrence in the recommendation which deprecated the propounding of harsh names, but he could hardly agree with the denunciation of what were called nonsense names, that was, names coined at random without any derivation whatever. The difficulty of devising generic names, not preoccupied, was immense: and if a person with a musical ear invented a nicely sounding word of classical form, surely it was as good as some cacophonous "jaw-breaker," whatever its derivation. Touching next on the comparative value of binomirl, trinomial, and quadrinomial systhms, he hardly thought the time had come for any radical interference with the binomial, which, notwithstanding all its defects, had worked so well from the time of Linnæus to our own. While condemning the practice adopted by some writers of coining new English names, he was in favour of appending the common names, where such really existed, to the scientific ones for behoof of the unscientific.—On the motion of Prof. Duns, a vote of thanks was accorded to the retiring President for his address and for his services in the chair.

Manchester

Literary and Philosophical Society, October 7.—A paper was communicated by Alfred Brothers, F.R.A.S., on the pink sun-glow which he had noticed at midday as early as January this year, and again on July 5 and at the end of August. On the evening of October 3 he observed the same phenomenon by clear moonlight, and attributed it, therefore, to our atmosphere, and not to its being a real appendage of the sun, as had been given out.

October 21.—Joseph Baxendell, F.R.S., communicated a note on the visibility of the moon during total lunar eclipses, in which it was sought to show that the visibility in question might in no inconsiderable measure be due to the outer corona, which extended to a much greater distance on each side of the sun than the semi-diameter of the earth as seen from the moon.—Prof. H. E. Roscoe, F.R.S., contributed a paper on the diamond-bearing rocks of South Africa. Two shafts sunk in the Kimberley Mine—one in the "pipe," the other in the shale near it—passed through the following strata:—

(1) "*Pipe*"		(2) "*Outside the Pipe*"	
Red Sand	3 feet	Red Sand	3 feet
Tufaceous Limestone	15 ,,	Tufaceous Limestone...	5 ,,
Soft yellow earthy diamond rock	30 ,,	Yellow Shale	20 ,,
Soft blue diamond rock proved to	282 ,,	Black carbonaceous do.	10 ,,
		Two thin bands of black dust in Shale... ...	1 foot
		Black Shale	236 feet
Total excavated ...	330 feet	Dolerite	2 ,,
		Total excavated ...	277 feet

The diamonds were found in the yellow and blue "Stuff" along with garnets, mica, bronzite, ilmenite, pyrite, &c., and were separated by washing the broken-up earth in sluices similar to those used in gold-mining. The annual value of the diamonds from Kimberley was said to be 3,750,000*l.*, and the total amount raised since 1870, to reach the enormous sum of 40,000,000*l.* Five different specimens of the strata were then produced and their analyses given.—Notes on envelopes and singular solutions (continued), by Sir James Cockle, F.R.S.

Paris

Academy of Sciences, November 17.—M. Rolland, President, in the chair.—On the breathing-bags of the *Calao rhinoceros*, by M. Alph. Milne-Edwards. The specimen of the species of hornbill forming the subject of the paper was brought to Paris last summer by M. P. Fauque, head of the scientific mission recently sent to Sumatra by the Minister of Public Instruction. Owing to the peculiar disposition of its breathing apparatus the *Calao rhinoceros* is a remarkably light bird, its weight scarcely exceeding 1500 grms., although it is about the size of a turkey.—On the anæsthetic action of the chlorhydrate of cocaine, by M. Vulpian. So powerful is this anæsthetic, which is at present the subject of numerous experiments by M. Koller and other physiologists, that an aqueous solution of one part salt of cocaïne and ninety-nine parts of water inserted under the eyelids produces complete insensibility of the conjunctiva and cornea in the human eye. But the effect, obtained in three or four minutes, lasts only a few minutes. Experiments made on the dog, frog, and other animals, have been attended with like results.—Contribution to the study of the deposits of phosphates (lime, iron, &c.), in the Departments of the Drôme, Isère, and other parts of South-East France, by M. P. de Gasparin.—Experimental demonstration of the inversion of the electromotor force produced by the contact of iron and copper at a high temperature, by M. F. F. Le Roux. From the results of several series of experiments, conducted under varying conditions, the author concludes that at about the temperature of 1000° an electric current passing from the copper to the iron heats the point of contact, while cooling it at the ordinary temperature. A knowledge of this fact, now for the first time demonstrated, may affect not only the theory of thermo-electricity, but also that of certain chemical phenomena.—Experiments made as a contribution to the study of the phenomena produced in man by the ingestion of the diarrhœic liquid of cholera into the stomach, by M. Bochefontaine. From these experiments, made on himself, as well as on the dog, guinea-pig, and other animals, the author feels justified in concluding that the reception in the stomach of the diarrhœic liquid containing the comma-bacillus of cholera does not neces-

sarily produce true cholera in man.—On the presence of the biliary salts in the blood of cholera patients, and on the existence of a toxic alkaloid in their dejecta, by M. G. Pouchet. The author, who is conducting a series of important experiments in the Hospital of Saint-Louis, Paris, concludes, so far, that the blood of cholera victims is certainly charged with a proportion, occasionally very considerable, of biliary salts, while their dejecta nearly always possess a strong alkaline reaction.—Letter on the application of the decimal system to the measurement of angles and of time, by the Minister of Public Instruction and the Fine Arts.—On a generalisation of the theory of mechanical quadratures, by M. Stieltjes.—On the reduction of the Abelian integrals, by M. H. Poincaré. It is shown that any system of Abelian integrals always differs infinitely little from a reducible system.—Note on the involution of superior dimensions, by MM. J. S. and M. N. Vanecek.—Note on an equation analogous to Kummer's equation, by M. E. Goursat.—A fresh demonstration of a theory of Jacobi respecting the decomposition of a number into four squares, by M. M. Weill.—On the laws of friction in mechanical appliances in connection with the experiments on the electric transmission of force about to be made between Paris and Creil, by M. Marcel Deprez.—On the construction of prototype standards of the legal ohm, by M. J. René Benoit. The International Conference of 1884 having defined the value of the legal ohm, the author describes some quicksilver standards representing the new unity constructed by him at the request of the Minister of Posts and Telegraphs.—Note on the indices of refraction of crystallised alums, by M. Ch. Soret.—On the chemical constituents of the rain-water that falls in the city of Algiers, by M. Chairy.—Remarks on the combustible carburetted compounds present in the terrestrial atmosphere, by MM. A. Muntz and E. Aubin.—Note on the trifluoride of arsenic, by M. H. Moissan.—On the reaction of ferric oxide at a high temperature on certain sulphates, by M. Scheurer-Kestner.—On ammoniacal ferment, by M. A. Ladureau. The author gives the results of experiments commenced three years ago for the purpose of determining the *rôle* and presence of this substance in Nature.—On the presence of amylase in the leaves of plants, by M. L. Brasse. The author has determined the presence of amylase in all leaves hitherto examined by him, including the potato, dahlia, maize, beetroot, tobacco, poppy, sunflower, &c.—On the employment of the cultivated yeast of wine for stimulating fermentation and shortening its duration, by M. A. Rommier.—Addition to a note on a crystallised pegmatite of chlorophyllite from the banks of the Vizézy, near Montbrison, by M. F. Gonnard.

BERLIN

Physical Society, October 24.—In former experiments with Helmholtz's leucoscope Dr. König had found that, while persons having normal trichromatic eyes saw the two images appearing in the field of vision differently coloured whatever the position in which the Nicol prism was placed, persons with so-called colour-blind or bichromatic eyes, on the Nicol prism being placed in a certain position, saw similar images. In the case of all so-called red-blind individuals the position of the Nicol prism was always the same, and differed from that in which green-blind persons saw like images. The leucoscope was, therefore, an instrument by means of which colour-blindness could be conclusively determined. For the practical requirements of eye-doctors, Dr. König had now so far simplified the leucoscope that it contained only a double prism, a lens, a quartz plate (of 5, 10, or 15 mm. thick), a Nicol prism, and a telescope. With the help of this simple instrument not only did it become easy to ascertain colour-blindness in practice, but it could likewise be determined whether any transitions occurred between red and green blindness. Among fifty colour-blind persons examined by Dr. Köng, he had not found a single case of such transitional form.—Prof. Neesen reported on the resumption of his earlier experiments regarding the influence of magnetisation on the electrical conductivity of fluids. The fluid conductor consisted of two tubes, a longer and a shorter, to which the current was transmitted by means of electrodes exactly alike. The tubes were combined into a bridge, and counterbalanced by the intercalation of metallic resistances. One tube was brought between the armatures of an electro-magnet, and the resistance measured alternately with and without the excited electro-magnet. When the tube was placed equatorially between the magnetic poles, the difference in the balance of the galvanometer was not greater than that produced on the galvanometer by the magnetising current alone (0·3 parts of the scale). With the tube placed in the axial position, on the other hand, the difference in the balance under an excited electro-magnet amounted to about 1 part of the scale, an effect which seemed to demonstrate a positive influence exercised on the conductivity by the magnetism, considering that the electro-magnet employed was not very powerful. It still remains necessary, of course, to determine by special experiments whether this change of resistance does not proceed from the influence exercised by the magnetism on the polarisation of the electrodes.—Dr. Kayser produced the lightning-photograph he had lately shown to the Meteorological Society (*vide* NATURE, vol. xxx. p. 652), and thereby gave rise to a somewhat lengthy discussion on lightning-discharges.—Prof. Eilhard Wiedemann of Leipzig communicated some results of an examination he had made into colloids, the relation of which to water, following up an earlier work on crystals and crystalloids, he determined with respect to their thermal behaviour. Lime on being brought into contact with water swelled, as was known, and that with evolution of heat. On dissolving slacked lime, on the other hand, in a larger quantity of water, heat became latent. Similar relations applied to other organic colloids, such as gelatine, starch, albumen, &c. The expansion of gelatine under heat Prof. Wiedemann found to be quite regular. At the melting-point of the colloids the curve of expansion showed only a very slight curvature convex to the abscissæ of temperature. When Prof. Wiedemann put some gelatine in a test-glass, and put on the top of it some small shot, and further placed a layer of gelatine over that, he saw, after heating, the shot slowly sink through the viscid mass to the bottom. If he now again spread some small shot on the top of the fluid gelatine, he again saw it sink slowly downwards. As soon, however, as it reached the place occupied by the previous shot before it sank to the bottom, its descent became much more rapid, as though the first shot had opened up a channel of lighter consistence in the gelatine which had been originally of the same consistence as the superincumbent gelatine.

THURSDAY, DECEMBER 4, 1884

THE CHOLERA BACILLUS

IN view of the investigations which are going on at the present time, it will be of interest to our readers to summarise the reasons which Koch gives for his conclusion that the comma-bacilli described by him are the cause of cholera. No doubt can remain in the minds of those who have read his paper on the subject, published in the *Berl. Klin. Wochenschrift*, No. xxxi., 1884, and the discussion thereon, that he has devoted an immense amount of time and labour to the question, and that he has dealt with the subject in a most open-minded and conscientious manner. His known character for accurate observation and care in drawing conclusions lend great weight to his statements. We will give a short sketch of his arguments under a series of headings.

(1) The comma-bacillus is a specific micro-organism having marked characteristics distinguishing it from all other known organisms.

Their length is from half to two-thirds of that of tubercle bacilli, but thicker and slightly curved: this curve is generally not more than that of a comma, but sometimes it may be greater, forming even half a circle. Sometimes several bacilli can stick together end to end, giving rise to the appearance of a spirillum. Koch thinks that this organism stands midway between a bacillus and a spirillum. They grow rapidly in meat infusion. They possess the power of active motion. They also grow well in other fluids, in milk more especially. They increase rapidly in blood serum. A very good medium is Koch's gelatinised infusion (peptone, gelatine, meat infusion, made neutral by carbonate of soda), and its cultivation in this material "renders its detection easy and very certain." Shaken up with the liquefied gelatine, poured out on a sterilised glass plate, and kept at a temperature at which the gelatine becomes solid, its colonies are very characteristic: when young, they appear as small, very pale drops, not quite round, but more or less irregular and jagged in contour; they also have a granular appearance, and when larger look like a heap of strongly-refracting pieces of glass; the gelatine becomes fluid in the immediate neighbourhood of the colony, the latter sinks into the gelatine, and thus a small funnel-shaped depression is formed, in the middle of which the colony is seen as a small white point. The liquefaction of the gelatine does not extend more than about one centimetre around the colony. If a tube of solid gelatine is inoculated by dipping a needle in the cultivation, and pushing it into the gelatine, the latter becomes fluid first at the point of entrance of the needle; the colony sinks more and more; a funnel-shaped depression is formed with an appearance as if an air-bubble were present at the top. They can also be cultivated in a meat infusion containing peptone, neutralised and rendered solid by agar-agar. They grow on potatoes, forming colonies closely resembling those of the bacillus of glanders, but not so brown as the latter. They grow best at a temperature between 30° and 40° C.; below 16° C. they cease to grow; freezing does not kill them. They only grow in presence of oxygen. They grow very fast; their vegetation rapidly reaches its highest point: it remains stationary for a time, and then as rapidly ceases, the bacilli dying. They will not grow in meat infusion or the gelatinised material if it is at all acid. They die very rapidly when dried, not retaining their vitality longer than three hours. They do not form spores, corresponding in this respect with spirilla rather than with bacilli; Koch has made an exhaustive series of investigations to ascertain this point. Micro-organisms presenting all these characteristics are the bacilli described by Koch; organisms presenting only some of the characteristics, such as microscopical appearance, but differing in other points, are not Koch's comma-bacilli.

(2) This bacillus is always present in cholera.

Koch states that this bacillus is always present in cases of cholera. He determines its presence not only by microscopical examination, but by cultivation in gelatinised meat infusion. In ten cases in Egypt they were found microscopically (he had not then worked out their characteristics on cultivation). In India he made forty-two post-mortem examinations, and found them in all cases, by cultivation and microscopical examination, in the intestinal canal. The dejections of thirty-two cholera patients were also examined in the same way, and the comma-bacilli were found in all cases; also, in two cases seen in Toulon, and microscopically in sections of the intestinal wall in eight cases sent to him previously from India and Egypt. In almost 100 cases carefully examined these organisms were found, and that in cases occurring in various parts of the world.

(3) It is the only form which is constantly present in this disease.

(4) It is present in greatest numbers in acute and uncomplicated cases.

Koch has found that this is the case, and that on the other hand, in cases which live longer, the bacilli are fewer, and more especially where hæmorrhage or other complications have occurred, other bacteria are most numerous.

(5) It is present in the parts most affected.

According to Koch the lower part of the small intestine is that most affected by the disease, and here the bacilli penetrate into the tubular glands and also in part between the epithelium and basement membrane; in some places they penetrated even more deeply into the tissue. Where death of portions of the mucous membrane had occurred, other bacteria were also present in the tissue, but the comma-shaped ones were always deepest, "giving the appearance as if they had prepared the way for the others."

(6) It is never present in other diseases, in healthy persons, nor has it been found outside the body when no cholera was in the neighbourhood.

This is the keystone of the research, and naturally Dr. Koch has devoted great attention to this point. All his investigations in this direction have been carried out by his usual methods—chiefly by cultivation, aided also by the use of the microscope. He has thoroughly examined thirty bodies of patients who had died of dysentery, intestinal catarrh, "biliary typhoid," one case of ordinary typhoid fever, and several cases where ulceration of the intestines has been present. In none of these did he find comma-bacilli. He failed to find them in a number of cases where he examined the dejections of patients

suffering from dysentery, also in diarrhœa of children, in animals poisoned by arsenic, in impure water from various parts around Calcutta, indeed wherever he met with a fluid containing bacteria he examined it for comma-bacilli, without however finding any (except in one instance, see No. 8). He specially mentions that he has tested saliva and the material on the teeth and tongue, which is always full of bacteria, but always with a negative result. He further refers to his own previous large experience in the cultivation of bacteria, and that of others who have worked at cultivation, this experience being against the presence of this organism, except in cholera. From these facts he feels himself warranted in stating that "the comma-bacilli constantly accompany cholera, and are never found elsewhere."

(7) No other conclusion can be arrived at than that these bacilli are the cause of cholera.

(*a*) It might be said that the choleraic process merely favours the growth of this bacillus. But on this supposition every one must have comma-bacilli in his body, because they are present in cases of cholera occurring in widely-separated parts of the world. This, however, is not the case (No. 6).

(*b*) As the result of the disease, conditions arise which cause the transformation of some ordinary bacterium into comma-bacilli. There is no evidence of such rapid transformation of one form of bacterium into another. The only known case of alteration in the properties of these bodies is the attenuation of anthrax bacilli, &c., but this is merely an alteration in pathogenic action; their form and mode of growth remain unaltered. Outside the body Koch has not, during the course of his investigations, got the slightest evidence of any change in these bacilli.

(*c*) The only conclusion which remains is that the cholera process and these bacilli stand in close relation to each other—in a relation of cause and effect.

(8) Although by experiments on animals direct evidence that the comma-bacillus is the cause of cholera has not been obtained, there are various observations which are almost as good as experiments on man.

In one case in a village near Calcutta Koch examined the water of a tank which supplied the inhabitants with drinking-water, &c. A number of cases of cholera had occurred, and when the water was examined the epidemic was at its height. Comma-bacilli were found in the water in considerable numbers. At a later period, when there were only few cases of illness, the comma-bacilli were few in number, and only found at one part of the tank. This was the only instance in which Koch found these bacilli outside the body. He further refers to the occurrence of disease in washerwomen, and infection from clothing soiled with cholera dejecta.

(9) The natural history of the disease corresponds with the various characteristics of this organism.

The bacilli grow rapidly, soon reach their highest point of development, and then die: this corresponds to what occurs in the intestinal canal. Under ordinary circumstances these bacilli are destroyed in the healthy stomach. This corresponds to the clinical facts of cholera, for, of a given number of individuals exposed to cholera, only some are taken ill, and those almost all suffer from disturbance of digestion—either catarrh of the stomach or intestine, or overloading of the stomach, &c., with indigestible food. The disease dies out in places where the conditions for its continuance are unfavourable: the bacilli have no spores.

These are the facts on which Koch's views are based; lately, however, two researches have been published which strike at the root of the theory, and which try to show that these bacilli are not peculiar to cholera. Dr. Koch has also published a reply.

The first of these researches is that of Dr. Lewis, who finds bacilli in the mouth microscopically identical with the comma-bacilli. Koch's reply (*Deutsche Med. Wochenschrift*, No. 45, 1884) is that he is well aware of the fact that organisms somewhat resembling the cholera bacillus are present in saliva, but that he does not diagnose these bacilli by microscopical characters alone, that if these bacilli are cultivated they will be found to be quite different from those present in cholera. For instance, they will not grow at all in the neutralised cultivating gelatine in which the cholera bacilli grow rapidly. The other research is by Finkler and Prior, who stated that they had found the comma-bacillus in cases of cholera nostras, and who further described spore-formation in them. Koch succeeded in obtaining a specimen of their "pure" cultivations, and found, on shaking up a minute quantity with the liquefied gelatine and pouring it out on a glass plate, that they had a mixture of four different bacilli, and that none of them were the comma-bacilli described by him.

Koch further adds the interesting fact that he has again taken up the experiments on the lower animals (presumably, from the context, on dogs and guinea-pigs), and that by injecting minimal quantities (as little as the 100th of a drop) of the cultivations of comma-bacilli into the small intestine, the animals have as a rule died in one and a half to three days, and the post-mortem appearances of the intestine were the same as in acute cases of cholera, the fluid in the intestine also containing enormous numbers of comma-bacilli.

In two cases of cholera nostras, and in a diseased bee, the writer found bacilli which microscopically closely resembled the comma-bacilli, but it was found that they did not grow in the neutralised gelatinised material, and were therefore not the same organism.

THE HAYTIAN NEGROES

Hayti; or, The Black Republic. By Sir Spenser St. John, K.C.M.G. (London: Smith, Elder, and Co., 1884.)

WHATEVER theory may be adopted regarding the fundamental equality or disparity of the human races, a truthful and unbiased account of the present social condition of the Haytians, by a competent observer, must necessarily prove a valuable contribution to the study of psychological anthropology. These conditions are eminently satisfied in the work before us, written as it is by a man personally above suspicion of any unworthy motive, by a statesman who has associated for some five-and-thirty years with every variety of coloured peoples, by a distinguished diplomatist, who, as British Minister and Consul-General, has resided for twelve years in Hayti itself. On the other hand, no more favourable field could be selected for a study of the negro race than this western and smaller division of this large West Indian island,

second in size only to Cuba, of which it forms a natural continuation eastwards to Porto Rico. Here the eastern and much larger division, known as Santo Domingo, has been mainly in the hands of a "coloured," that is, negroid or mulatto people, since the expulsion of the Spaniards and French early in the present century. But in Hayti the pure negro has always been in the ascendant, and his policy has persistently been to get rid of the white and coloured elements. The whites disappeared, either exterminated or driven into exile, during the struggle with France; and of the present population, roughly estimated at some 800,000 or 900,000, not more than one-tenth are mulattoes, and all the rest full-blood Africans. The Haytians may, in fact, be regarded as a section of the negro race transplanted bodily to their present domain, where they have had it all their own way since the close of the last century. Whatever differences may exist, are all in their favour; for they here find themselves separated from the old baneful associations, and surrounded on all sides by the civilising influences of more cultured peoples. The physical environment is also more favourable, the climate being on the whole decidedly superior to that of the African sea-board, while the well-watered lowlands are described as amongst the most fertile tracts on the globe.

And what is the outcome of fully three generations of political autonomy under these exceptionally advantageous conditions? Practically a reversion to, or, more correctly speaking, an almost uninterrupted perpetuation of, the African tribal organisation in its very worst aspects. Such is the general conclusion conveyed by a careful study of Sir S. St. John's work, which may be briefly described as a formidable indictment against the negro race as such, and a crushing reply to those sentimental philanthropists who go about preaching the doctrine of the inherent equality of all mankind. In a few well-digested chapters he deals comprehensively with the history, government, trade, industries, and social institutions of the "Black Republic," and on all these branches of the question his verdict is in the highest degree adverse. "I could not but regret," he writes, "that the greater my experience the less I thought of the capacity of the negro to hold an independent position. As long as he is influenced by contact with the white man, as in the southern portion of the United States, he gets on very well. But place him free from all such influence, as in Hayti, and he shows no sign of improvement. On the contrary, he is retrograding to the African tribal customs, and without exterior pressure will fall into the state of the inhabitants of the Congo. I now agree with those who deny that the negro could ever originate a civilisation, and that with the best of education he remains an inferior type of man. He has as yet shown himself totally unfitted for self-government, and incapable as a people of making any progress whatever. To judge the negroes fairly, one must live a considerable time in their midst, and not be led away by the theory that all races are capable of equal advance in civilisation" (pp. 131-132).

This general conclusion is amply supported by overwhelming evidence collected at first hand by a shrewd observer, whose official position enabled him to obtain accurate information regarding every phase of Haytian political and social institutions. That the successive "empires" and "republics" were mere burlesques; that the administration of justice has always been a farce; that civic virtues are absolutely unknown; that, in a word, "politically speaking, the Haytians are a hopeless people" (p. 133), will probably be accepted without demur by the intelligent reader. But that fetish worship, cannibalism in its most repulsive forms, and all the abominations associated with the secret "Vaudoux" rites, are still rampant, and encouraged if not actually practised by the very highest State functionaries, including Presidents themselves, would certainly be received with a smile of incredulity, were the facts not attested by evidence of the most unimpeachable character. Even so the revelations made in connection with this loathsome subject almost exceed the bounds of belief, and could not be accepted, were we not assured that they are "founded on evidence collected in Hayti, from Haytian official documents, from trustworthy officers of the Haytian Government, my former colleagues, and from respectable residents—principally, however, from Haytian sources" (Introduction).

To the question, Who is tainted by the Vaudoux[1] worship? the answer is, "Who is not?" Yet a prominent feature of this horrible cult is the sacrifice of "the goat without horns," that is, of some human victim, often supplied by the parents themselves, who also share in the feast at which their murdered offspring is devoured. At a trial held in 1864, four women were convicted on their own confession of having killed and eaten a girl, six years old, delivered to them by the aunt, and of feeding up another child to be sacrificed and eaten on the Feast of the "King of Africa." A Spanish official present at the trial reported that, if the public prosecutor had done his duty, "not only the witnesses but the mother of the victim herself would have shared the fate of the cannibals proved guilty of having eaten her." Another woman, reproached with having devoured her own offspring, retorted, "And who had a better right? Est-ce que ce n'est pas moi qui les ai fait?" And in 1878 a case came under the notice of the author, in which two women were caught in the act of eating the flesh of a child raw. "On further examination it was found that all the blood had been sucked from the body" (p. 225).

In common with many other observers, the author noticed "that negro boys up to the age of puberty were often as sharp as their coloured fellow-pupils," adding that "there can be no doubt that the coloured boys of Hayti have proved, at least in the case of one of their number, that they could hold their ground with the best of the whites" (p. 266). But it is equally certain that after reaching puberty further progress appears to be arrested, so that the negro remains intellectually a child to the last. This remarkable phenomenon is probably due to the premature closing of the cranial sutures in the negro race, as suggested by Filippo Manetta, who also noted the sudden arrest of development in adults. "The intellect seemed to become clouded, animation giving place to a sort of lethargy, briskness yielding to indolence. Hence we must needs suppose that the evolution of the negro and white proceeds on different lines. While with the latter the volume of the brain grows with the expan-

[1] Apparently a corruption of the West African word *Vodun*, implying a species of ophiolatry, in which the great serpent, an all-powerful supernatural being, on whom all things depend, is worshipped by secret rites, nocturnal orgies, and human and animal sacrifices.

sion of the brain-pan, in the former the growth of the brain is on the contrary arrested by the premature closing of the cranial sutures and lateral pressure of the frontal bone."[1]

The chapter on the curious French Creole patois current amongst the Haytians will be found instructive by students of such jargons. Its euphonic laws and peculiar structure, or rather absence of structure, are illustrated by a number of passages from popular songs and proverbs, such as the characteristic—

> "Négue riche li mulatte,
> Mulatte pauvre li négue."

That is—

> "Negro enriches mulatto,
> Mulatto impoverishes negro."

Beyond oral compositions of this sort there is no local literature, and the public records, diplomatic communications, and correspondence of all sorts are written in more or less grammatical French. None of the full-blood blacks have aspired to the honours of authorship, or attempted any sort of literary composition beyond an occasional political essay or manifesto. In this as in all other respects there seems to be an impassable gulf even between them and the coloured portion of the population.

The book is furnished with a useful map of Hayti; but there are neither illustrations nor index.

OUR BOOK SHELF

Hilfsbuch fur den Schiffbau. Von Hans Johow. (Berlin: Julius Springer, 1884.)

THIS handsome volume belongs to the class of publications known as "pocket-books," of which there are many examples, in English, adapted to the use of various branches of engineering. It is essentially a compilation of facts, formulæ, and methods likely to prove useful to ship-builders in the course of their ordinary work; and it will bear favourable comparison with anything of the kind previously published. In the range of its information, and the extent as well as variety of the sources drawn upon, Mr. Johow's book surpasses all others intended for the use of ship-builders; evidencing wide research and a thorough acquaintance with the literature of the profession. It cannot fail to prove valuable as a book of reference in the offices of all ship-yards, and should be of great assistance to draughtsmen, especially in carrying on calculations or details of design.

Tbe arrangement of the book is excellent, and it is admirably produced, the numerous tables and diagrams, as well as the mathematical investigations, being clearly printed and easily followed in reading. This has been accomplished without making the volume large or expensive. Five principal sections embrace the contents.

The first section contains a mass of general information and tables, designed to facilitate reference and save labour. In the mathematical subdivision of this section appear tables of the squares, cubes, square root, cube root, &c., of numbers up to 1000; trigonometrical tables; algebraical and trigonometrical formulæ of various kinds. Another subdivision deals with "mass and weight," giving full particulars of the weights and measures of various countries, and tables for conversion of one system to the others. Tables of weights of materials follow, and are very extensive and well arranged; in addition, there is a brief summary of the principles of strength of materials, including Wöhler's valuable investigations on the "fatigue" of metals. Brief chapters are also devoted to the theory of heat, chemistry, and galvanism; and finally a good deal of information is given on details of design, fastenings, &c.

The second section deals with the theory of ship-building. It gives particulars of various systems of mechanical construction for the forms of ships; deals with the problems of buoyancy and stability, and describes methods of calculation; gives approximate formulæ for use in preliminary investigations; and deals in a practical fashion with ocean waves, propulsion of ships by sails, the action of the rudder, fluid resistance, and propulsion by steam power. Under the last heading appears a most comprehensive summary of the various methods proposed for approximating to the engine-power required to give steamships their assigned speeds. Lastly there is a chapter on compass-correction.

The third section deals with more practical questions relating to the lading and freeboard of ships; their outfit of anchors, chains, boats, pumps, &c.; the armaments of war-ships; the methods of testing materials used in ship-building, &c.

In the fourth section are contained detailed information relating to the propelling machinery, boilers, and propellers of ships; the rules of the Board of Trade for boilers; and tables, &c., for use in trials of speed.

The fifth and last section contains details of the laws and regulations affecting German and foreign shipping, various rules for calculating tonnage, and our Board of Trade regulations for passenger-steamers. An excellent index concludes the book.

It cannot be supposed that such a great mass of information has been brought together and greatly condensed without some sacrifices and possible errors; but the author has evidently taken pains to insure accuracy, and his book should command a wide circulation both in Germany and abroad.

W. H. W.

A Synopsis of Elementary Results in Pure and Applied Mathematics: containing Propositions, Formulæ, and Methods of Analysis, with Abridged Demonstrations. By G. S. Carr, M.A. Vol. i., Sections x., xi., xii. (London: Francis Hodgson, 1884.)

OUR notices of the former sections will be found in vol. xxii. (p. 582) and vol. xxvi. (p. 197). These sections are occupied with the Calculus of Variations (pp. 441 to 459), Differential Equations (pp. 460 to 545), and the Calculus of Finite Differences (pp. 546 to 560). In the first section we have not detected any mistakes of any importance, in fact only one or two typographical faults. The second section commences with an unfortunate slip in the numbering of the articles, which is not pointed out until the next sheet is commenced (p. 473). In this section there are numerous errata, of which we indicate a few. In § 3276 the first term in the last line should have the mark of differentiation with regard to x affixed. We note mistakes in §§ 3342, 3382, 3392, 3394, 3399, 3407, 3431, 3447, 3499, 3520, 3521, 3537, 3570. These corrections are mostly for wrong references, and the articles are cited for the benefit of students. The last section appears to be quite right, with the exception of a typographical error in § 3703. We have not undertaken to work out and verify each article, but we have gone through each, and the above small list of mistakes will give an idea of the care exercised in the editing of this part. We repeat our former advice, viz. that a student who wishes to refer to the "Synopsis" for refreshing his knowledge of the above-named branches should at the time of his reading his text-book have this manual by him for verification. The sections are mainly based upon Jellett (for Variations), and Boole (for the two latter sections).

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Natural Science for Schools

I WAS glad to see that "Science Master" had pointed out some of the difficulties in the way of applying the principles laid down in Prof. Armstrong's valuable paper in your number for November 6 (p. 19). The difficulties to which he has adverted relate mainly to those gratuitously thrown in the way of sound and useful practical teaching in grammar-schools by boards of examiners. Another difficulty I ventured to point out in the brief discussion upon Prof. Armstrong's paper at the Educational Conference of the International Health Exhibition, but it did not receive the attention which I think it deserved—partly, perhaps, owing to press of business, and partly, perhaps, also to the fact of the naturally somewhat strong representation of South Kensington interests at a conference held within the shadow of the Brompton Boilers. Prof. Armstrong appeared specially to recommend his mode of teaching "in science classes, such as those held under the auspices of the Science and Art Department," and towards the end of his paper he seems to recognise only one difficulty in the way of introducing it generally, viz. it "undoubtedly involves more trouble to the teacher than that ordinarily followed," and he appears to hint that the present method is mainly due to the incapacity of the teacher, as he says, "I do not believe that it is because the Department consider it" (the system) "a satisfactory one; but they know full well that it would be unwise to legislate far in advance of the intelligence and powers of the majority of the teachers." There are many teachers who are only too anxious to teach, not chemistry merely, but physics and other branches of science upon a sensible system, and who would willingly take considerable *trouble* to attain that end, but the difficulty is that, were they to do so, they would not get paid for their work. The insane system of *payment by results* is responsible for the greater part of the bad and indifferent teaching of science in this country, and the real trouble is, not that something better is in advance of the intelligence and powers of the majority of *teachers*, but that it is in advance of the intelligence and powers of the majority of *examiners*. The Department accept as their primary axiom that no teaching is to be paid for except that which can be exactly tested and appraised by certain examiners; and so no teaching, whatever its educational value, is counted worth anything by them except that which is susceptible of being weighed and measured. I took the liberty at the discussion of asking Prof. Armstrong whether he had ever taught a class on his methods, and if that class was presented to the Department for examination, and if so what was paid for it, and I made bold to express my own opinion that the result would be either *nil* or despicably small. My question received no answer, but I got plentifully snubbed—firstly, that a science teacher should even think of such a subject as remuneration, and secondly, I was informed that practical teaching always paid best. But as it appeared that my critics had misapprehended the point at issue, and were not speaking of the kind of teaching advocated by Prof. Armstrong at all, but thought that *practical* teaching meant allowing the class to see certain experiments performed by the teacher himself—a mode of teaching which I am quite agreed with the reader of the paper in considering quite *unpractical*—I did not feel satisfied that my question was answered, and with your permission will again propound it. It is not a sufficient answer to say that the most practical teachers earn the best results—I am a science teacher of quite sufficiently long experience to know that—*provided it is strictly on the lines laid down by the Department*. What I doubt is whether *sensible* practical teaching would produce any pecuniary results.

Certainly, in what is called (*lucus a non lucendo*) practical chemistry it would not: there nothing but test-tubing can be weighed and measured; and whereas in former years a knowledge of the modes of preparing and experimenting with certain of the more common elements and compounds counted for something in the elementary stage, it has lately, by successive alterations in that direction in successive issues of the Directory, become more exclusively test-tubing.

In physics I presume the intelligent teacher would be glad to teach his class in light, heat, and sound, to make some of the more important measurements, to verify the laws of reflection and refraction, to measure the refractive index of glass, to calculate the foci of various lenses, to determine the latent heat of water and steam, and the specific heat of one or two substances and a few other similar things, not many of which could be introduced in a course of thirty lessons of one hour each; in electricity and magnetism, to establish the laws of intensity, to construct an electroscope, a galvanometer, and a Wheatstone's bridge, to measure the resistance of a few lengths of wire, to determine the E.M.F. of a "cell," &c., in which case the same limits would soon be reached. But would such a course pay? I venture to say not, and the Department have not even given to practical physics the scant encouragement which they afford to so-called practical chemistry. I say *scant encouragement*, because, by a series of red-tape regulations, which are strictly adhered to, they do their best to render the study of practical chemistry needlessly expensive to the committees and unremunerative to the teachers.

I shall probably be told—firstly that the teacher of a science class has no need to limit himself to thirty hours for a course; and secondly, that he should not make remuneration his first consideration. On the first point I reply that he is practically limited in most cases by the length of time during which it is possible to get students to attend: the month of September is as early as it is practicable to commence a course, and the examinations are early in May, so that one lesson a week, allowing for necessary holidays, cannot much exceed thirty lessons. To give two lessons per week would be to occupy the time of two classes for the remuneration—generally poor enough—of one; this, of course, virtually brings us to the second point, as to which I would say that, as in other professions men do not work for inadequate remuneration, I do not see why the science teacher should be expected to be more philanthropic; that neither the clergyman, the lawyer, nor the physician professes to regard money as his chief consideration, yet that the remuneration of each of these professions is far before that of the science teacher, at all events of him who works for the Science and Art Department; and lastly, that that particular line of criticism does not usually come from those who are themselves working from philanthropic motives, but from those who are pretty well paid for their labours, and who would despise the modest reward of the "*payment by results*" teacher.

I hope I shall not be misunderstood as disagreeing with Prof. Armstrong's views; it is, on the contrary, because of my full agreement with them and that I am anxious that those science teachers who are sufficiently advanced in intelligence (and I am persuaded that they are not so rare as Prof. Armstrong seems to think) to adopt a truly educational mode of teaching, should have no needless obstacles thrown in their way, that I venture to address you and to repeat before a larger audience those arguments which I made use of before the smaller auditory at the Health Exhibition.

I for one should be only too glad to see the scope of the science teaching under the Science and Art Department widened, and to know that encouragement was given to the intelligent and advanced teacher to get out of the grooves in which it appears to be the present policy of that Department to retain him.

WALTER A. WATTS

Farnworth Grammar School, November 20

Do Flying-Fish Fly?

I CANNOT pretend to the great experience of Mr. R. W. S. Mitchell in observations on aërial movements of the flying-fish when for a brief space he leaves his native element; but during one voyage from the Isthmus of Panama to England *viâ* the West Indies I lost no opportunity (of many) of watching these beautiful creatures, sometimes very close indeed to our steamer. The opinion I formed at the time and still retain was that there was constant very rapid motion of the great lateral fins whilst out of the water, so rapid, indeed, that the strokes of the fins could not be counted. From what Mr. Mitchell says, he evidently counted the strokes of the wings (pectoral fins), not by seeing the movements of these, but by the "impressions made on the oily surface of the water," impressions apparently similar to those made by a cormorant or other diver when taking wing from the sea.

The movements of the side fins whilst the fish was in the sea or touching the surface, would be much slower than would be the

case when it was wholly in the air, because, to be of any use then, the strokes would have to be so rapid as to be scarcely countable, as is the case with certain sea fowl (notably auks) which use their wings (with a comparatively slow stroke) whilst swimming *under* water, but when flying move them so rapidly that the strokes can either be counted with difficulty or not at all. On watching flying-fish whilst in the air, I noticed a flickering of the fins, indicating what I believe to have been rapid motion.

As Mr. Mitchell's observations, on which he chiefly relies, were made when looking down from the high bows of a steamer, the "waving from side to side" of the tail of the fish, being a lateral motion, was clearly seen, whilst the movements of the side fins would be less easily discernible.

Finally, could the impetus acquired by the fish, when springing from the water, carry it through the air "50 or 100 yards" (Mr. Mitchell's estimate) without the aid of any additional propelling force during its fight? If so, the initial velocity must have been very great. JOHN RAE

4, Addison Gardens, W., November 27

The "Jeannette" Drift

IN NATURE of November 20 (p. 66) you give an account of the finding of some relics of the *Jeannette*, which have been picked up on an ice-floe at Julianhaab, in lat. 61° N., long. 46° W., near the south point of Greenland, and which must have drifted from the New Siberian Islands in lat. 75° N., long. 155° E., where the *Jeannette* was squashed three years ago. This I consider a most important find with regard to Arctic navigation and discovery. The question arises, How did the ice-floe get to Julianhaab? I propose the following solution. The Siberian Islands bear nearly due north from Julianhaab, and in a straight line up Davis's Strait, Baffin's Bay, Smith's Sound, Lincoln Sea, &c., and across at a distance of about 250 knots from the Pole. I think it most probable that the floe may have drifted through "the unknown," or what Osborn calls "the land of the white bear," the large unexplored area to the west of Banks's Land, and have got into Baffin's Bay through one of the sounds on its west coast—either by Jones's Sound, where the tide runs eastward at the rate of two knots an hour ("Inglefield," p. 77), or by Banks's Strait and Lancaster Sound.

We know that the icebergs come *down* Baffin's Bay and Davis's Strait into the Atlantic, and the floe has had fair success in navigating through a distance of 2700 knots to reach Julianhaab in three years.

I cannot for a moment suppose that this ice-floe has come from the Siberian Islands, *viâ* Francis Joseph Land, Spitzbergen, Iceland, to Greenland, a distance of 3600 knots, for that course would have been directly *against* the Gulf Stream, in which no floe could last three years, even if it were 26 feet thick, as Inglefield found them in Jones's Sound, or 40 feet thick, as McClure found them in Banks's Strait. McClure found the current west of Point Barrow going 2 knots per hour to the south, evidently making for Behring's Strait, while of the north-west point of Banks's Land the drift was north-east 1 knot an hour, evidently going towards Lancaster Sound.

I therefore conclude that the *Jeannette* relics could not have come westward, they *must* have come eastward, and this proves that there is a course open which is unknown to us.

I would suggest that a number of very strong buoys, capable of resisting ice-pressure, should be set adrift on ice-floes on various parts of the Siberian coast, each numbered indelibly, so that when recovered it could be ascertained whence they started, and their course *might* possibly be ascertained from the Eskimo, who may have seen them, or by other means. This experiment is worth a trial. R. S. NEWALL

Ferndene, November 30

A Meteor Visible in the Daytime

AT Waterpark, just below Waterford City, about 4 p.m. on October 15, my attention was attracted by a flash of increased light. Looking up, I saw in the south-south-west, about half way between the horizon and the zenith, a bright meteor slowly sailing nearly due west, its apparent size about half that of the full moon, intensely white in colour at the centre, passing into blue at the circumference. It described a low arc, and was in sight for several seconds, leaving a trail of indigo blue with lighter luminous edges. The meteor disappeared behind some clouds which concealed the sun at a considerable altitude above the horizon. JAMES GRAVES

November 27

Noon-Glow

WHILE waiting at the telescope shortly before noon this date to note place of sun-spots at meridian passage, masses of cloud formed suddenly in a clear sky overhead, and drifting slowly due south, obscured a peculiarly brilliant sun. No sooner had direct light been intercepted than the upper air above cloud and sun's place appeared filled with the latterly common white glare (as of attenuated peat-smoke highly illuminated), which soon became suffused with the now familiar rose-tint, apparent also between the clouds and on south-south-west horizon, but not beneath the sun on meridian. The sun's apparent meridian altitude being 16°, the superior limit in altitude of rose-tint was 39°; the colouring being monotone throughout, and not to be confounded with that of halos. Fearing ocular deception, as often happens from fatigue of eyesight, I asked an intelligent companion to verify observation, more especially as the diffused white glare at first slightly masked the tinting as compared with that of other "glows." It seems, however, plain that the terms "fore-glow" and "after-glow" no more cover the entire field than the Krakatoan dust. D. J. ROWAN

Kingstown, November 24

Rosy Glow about the Moon

AFTER watching for some time this evening a lovely twilight in the west, which though bright and luminous was not remarkable for strong colour, I turned toward the south-east, when the moon, now well up, was shining through detached fleecy clouds, and was surprised to see about her a rosy-coloured glow, very like that so often seen about the sun; the nearer clouds, though very high, telling as a cold almost greenish grey upon it. This glow, of course, was much lower in tone than that about the sun, but both in character and extent just like it, and quite distinct, and broader than those prismatic hues often seen about the moon, and called by sailors "cock's eyes" or peacock's-eyes. This was at 4.45 p.m., and as the twilight faded the glow disappeared, from which I infer that it was caused by vapour lying high enough in the south-east to catch some of the very last rays of the sun, but too far east to give a glow in the west.

I see that a correspondent of the *Standard* telegraphed that on the evening of the 25th "a sunset equal in splendour to those of last autumn was seen over the Yorkshire wolds. The predominating hue was a rich crimson." The weather here was cloudy that evening, but between narrow openings in the clouds the sky was the colour of rich painted glass of a ruby-red tint about 4.30 p.m. ROBERT LESLIE

6, Moira Place, Southampton, November 28

Wild Fowl Decoy

MAY I ask if any of your readers who are interested in wild-fowl decoys will send me the names and positions of any past and present ones they may happen to know or have heard of. I am endeavouring to save the history of decoys from oblivion, and though I have many hundred letters, maps, and sketches connected with this interesting subject, still I may have a great deal of information yet to obtain. I think the subject deserves a standard work, or I would not trouble you.

RALPH PAYNE GALLWEY

Cowling Hall, Bedale, November 24

Prehistoric Man

DURING October last, the sanitary authorities of Gloucester City had occasion to make some excavations in the timber-yard of Messrs. Booth and Co., and in the Bristol Road adjoining this yard, for the purpose of laying down a new sewer. In the course of this operation the workmen disinterred, from a bed of plastic clay, three human skeletons, occupying a position which appears to suggest that the remains in question are probably those of prehistoric man.

Arriving accidentally on the spot some two or three days after the actual find, I learned, to my great regret, that the skulls, two of which had passed through my friend Mr. Wm. Booth's

hands, had been cast on one side, reduced to fragments, and finally buried in the concrete foundation of the new sewer, no one supposing that the discovery represented anything more than some modern interment.

My friend had, however, seen one of the skeletons complete and *in situ*, extended at full length, face downwards, in the clay, while I succeeded in gathering a basketful of bones, including fragments of four left-hand femora, thus, probably, attesting the presence of more individuals than the number to which the workmen deposed.

Some of these bones I extracted from the clay itself, the remainder being found among the excavators' ejecta. Almost all of them are broken and have their cavities, even the spongy tissues and diploë of the cranium, completely filled with the clay in which they were discovered. They are easily broken into fragments by hand, have little organic matter remaining in them, and a few exhibit indications of having been gnawed by animals.

The clay-bed itself showed no signs of disturbance, such as would indicate a burial. On the contrary, it was evident that the bones had been quietly covered with river deposits as they lay, and, although near each other, the skeletons did not occupy a common resting-place.

The remains occurred at a depth of 5 feet 6 inches below the surface, 36 feet above Ordnance Datum, and 3 feet above the highest known modern flood-line, given on the authority of Mr. Martin, engineer to the Severn Navigation Commissioners.

It is clear, therefore, that the clay-bed in question must have been deposited at a time when the River Severn ran, and its flood-loams were laid down, at levels higher by many feet than those of the present day, or, in other words, at some time antecedent to the historic period, during which there is no reason to suppose that our rivers ever met the sea except at existing horizons. DANIEL PIDGEON

Holmwood, Putney Hill, November 22

Fly-Maggots Feeding on Caterpillars

AFTER Mr. McLachlan's remarks in NATURE for November 20 (p. 54), on Dr. Bonavia's note upon the above subject, it is hardly necessary to say that your correspondent, F. N. Pierce (November 27, p. 82) is undoubtedly mistaken in saying that he has bred the house-fly, *Musca domestica*, from Lepidopterous larvæ. If he has really bred *Musca domestica*, it is a new fact, and I should be very glad to see a specimen. I have had some considerable experience in breeding Lepidoptera, and have frequently bred out Dipterous parasites; these have invariably been *Tachinids*, mostly of the genus *Exorista*. To the ordinary observer they very closely resemble *Musca domestica*, but the same observer would very probably call all the various species of *Musca*, *Anthomyia*, *Homalomyia*, *Stomoxys*, &c., which frequently occur in houses, "house-flies." The general appearance of many of these genera is very much the same, and the term "house-fly" is such a vague one that I remember a good microscopist once showed me a slide labelled "upper and lower wing of house-fly"! some Hymenopteron caught on a window apparently furnishing the materials.

The Diptera are unfortunately much neglected in this country, and many groups are very little known. This is especially the case with the *Tachininæ*, and Lepidopterists who breed them would benefit science by pinning the specimens and sending them to one or other of the few students of this order of insects.

4, East Street, Lewes, November 29 J. H. A. JENNER

YOUR correspondent, Mr. F. N. Pierce, in NATURE for November 27 (p. 82) merely continues the error suggested by Dr. Bonavia's note on this subject. It is not the larvæ of the house-fly (*Musca domestica*) that he has found as parasites on his butterfly and moth caterpillars, but the larvæ of a *Tachina*, a Dipterous genus of the *Muscidæ*, too well known among even mere collectors, I should have thought, for such a mistake to be made. There is of course a superficial resemblance.

M. E. S.

The Forbes Memorial

MAY I make use of your widely circulated pages to say that I purpose in a few days to send to press a list of the subscribers to the Forbes Memorial, to be bound up with the issue of the zoological memoirs of our lamented friend; the Memorial Volume is now nearly ready, and I shall be glad to hear from any of the friends of Mr. W. A. Forbes who have not already communicated with me on the subject. May I add that it was agreed by the Committee that subscribers should receive a copy of the volume for every guinea subscribed.

F. JEFFREY BELL

5, Radnor Place, Gloucester Square, W.

THOMAS WRIGHT, M.D., F.R.S.

IT is perhaps hardly sufficiently recognised how much the progress of science has been helped by the leisure-hour occupations of busy professional men. No branch of science has profited more from this source than geology, and no calling has furnished so many helpful labourers as medicine. The career of Dr. Wright, whose recent death is so sincerely regretted, supplies one of the most notable examples of a life apparently absorbed in the laborious duties of a medical practitioner, yet wherein time was found for the pursuit of a long series of original and valuable researches in palæontology. To those who knew him only as a doctor, it might well seem that his whole time and thought were given to the duties of his medical practice. Those, on the other hand, who met him as a geologist and palæontologist could hardly realise that he had any other occupation than the study of the fossils which he treasured and described with such enthusiasm.

Dr. Wright was born in Paisley in 1809. Having a near relative engaged in the practice of medicine, he chose the same profession for himself, and received the earlier part of his education at Glasgow. Before he had completed his studies, he was induced to quit medicine and take part in the development of the manufacturing arts, then making rapid strides in Scotland. But finding the change unsuited for his temperament he turned back with a sense of relief to the profession he had abandoned, resumed his medical studies in Dublin, and finally graduated in 1846. Soon thereafter, circumstances led him to settle in Cheltenham, where he has since spent the whole of his long and honoured life. His devotion to the healing art, and his bent towards a scientific treatment of his subject, were soon recognised, and he became successively attached to the Dispensary and General Hospital, and finally Medical Officer of Health for Cheltenham and surrounding districts. He was twice married, and leaves a son and two daughters by the second marriage.

In the early days of his career Dr. Wright manifested his love for scientific investigation. While still a student in Dublin he devoted himself with ardour to the study of human anatomy, and especially to the application of microscopic research in that department of inquiry. His eyesight, however, not proving strong enough to bear the strain of microscopic work, he finally exchanged that pursuit for the cultivation of palæontology, which from the position of Cheltenham in the midst of richly fossiliferous rocks, lay temptingly open to him. Ranging over the abundant organic remains of the Lias and Oolites of his neighbourhood, he chose the Echinoderms as his special subject, and began to publish the results of his observations. His early papers gained for him the friendship and co-operation of Edward Forbes. It was arranged that the two naturalists should conjointly describe the Echinoderms of the British Secondary formations, Forbes taking the Cretaceous, and Wright the Jurassic forms. The former did not live to carry out his part of the programme, which was accordingly completed by his colleague. The monographs on the Secondary Echinoderms were published by the Palæontographical Society, and form an enduring monument of Dr. Wright's patient and minute research. But while engaged in these investigations, he did not neglect other departments of Jurassic palæontology. In particular, he devoted himself with

unwearied industry to the collection and comparison of the Cephalopods of the Lias, and at length, after some forty years of preparation, began his great monograph on "The Lias Ammonites," a work of much research, of which the concluding part is about to be issued, and which forms an enduring landmark in the history of English palæontology. In the course of the inquiries rendered requisite for this exhaustive treatise, he not only made himself acquainted with the fossil localities and public and private collections in this country, but paid visits to many parts of the Continent to study the contents of foreign museums and to confer with his fellow-labourers in the same field scattered over France, Switzerland, and Germany. He was engaged, at the time of his death, upon a monograph of British Cretaceous Starfishes, which he had nearly completed.

The value of his scientific work has been fully recognised by his contemporaries. He was early elected as a Fellow of the Royal Society of Edinburgh. Subsequently he joined the Geological Society of London, and from that body eventually received its highest honour—the Wollaston Medal. In 1879 he was elected into the Royal Society. He was President of the Geological Section of the British Association at the Bristol meeting in 1875. His published papers and memoirs are numerous, but the largest and most important are his monographs in the publications of the Palæontographical Society.

It was not alone by original research that Dr. Wright strove to foster the progress of his favourite science. As one of the fathers of the Cotteswold Field Club, as President of the Literary and Philosophical Association of Cheltenham, as a frequent lecturer on scientific topics not only in Cheltenham, but in Bristol, Bath, Worcester, and other towns; and generally by the enthusiasm with which, amid all the obstacles of his busy professional life, he contrived to find leisure for the cultivation of science, he was unquestionably one of the living forces that stimulated the growth of science all over the West of England. His death is therefore a serious deprivation, and will be mourned by all in that region to whom scientific progress is dear.

To a narrower but still a wide circle his removal from among us is the loss of a leal-hearted friend. Those who were thus privileged will cherish the memory of that cheery face with the bright twinkle of eyes that were as brimful at one time of merriment as, at another, they were suffused with sympathy; the joyous laughter that rang out clear and strong from a heart in which there was no guile; the earnest brow and hand upturned behind the ear as the talk went on over his favourite pursuits; the bursts of enthusiasm as some new fact or novel deduction dawned on him, and the play of humour that was ever ready to break out like a beam of summer sunshine. Dr. Wright made his final expedition in August last year, when he joined the writer of these lines in the Island of Arran. Already the symptoms of his fatal malady had shown themselves, and he knew what they foreboded. But he carried with him nevertheless his characteristic sunniness of nature. Seated on the bare mountain-side with the purple heather and yellowed bracken around him, the sea in front, and his own native Renfrewshire hills in the blue distance, he became almost a boy again as he told his reminiscences of old times and watched the sports of children among the gray boulders. Ripe in honours as in years, it seemed as if he had come back to his early northern air to drink it once more, and review his past before he should quit us for ever. He would saunter for hours in the quiet glen, with no companion but his own thoughts and the sights and sounds of Nature, which were an ever-gushing fountain of pleasure to him. Cherished is every memory of him, but most of all those parting days spent with him at the foot of the mountains and by the shore of the restless sea.

A. G.

ROBERT A. C. GODWIN-AUSTEN, F.R.S.

IN many respects Mr. Godwin-Austen stood out apart from his fellow-geologists in this country. He wrote comparatively little, but what he did write was always weighty and full of suggestiveness. Instead of loading the literature of science with a pile of little papers, each containing some trifling addition or supposed addition to the sum of knowledge, or some criticism well- or ill-founded of the work of others, he allowed his ideas to mature, and published them from time to time in luminous essays which many years afterwards may be read over again with profit as well as pleasure. He began to write about half a century ago, his earliest papers being devoted to the geological features of Devonshire, of which, at that time, very little was known. By degrees he extended the area of his observations eastwards into the south-eastern counties. His essays "On the Valley of the English Channel" (1850), and "On the Superficial Accumulations of the Coasts of the English Channel, and the changes which they indicate" (1851), were among the most thoughtful contributions that had ever been made to the elucidation of the existing outlines of sea and land. This department of inquiry was one that peculiarly fascinated him. Hence, when his friend Edward Forbes died and left his "Natural History of the European Seas" only half completed, he himself chivalrously finished it, and supplied some chapters which only an accomplished and far-sighted geologist could have written. His various papers on drift-gravels, on boulders in the Chalk, and other superficial phenomena, are all marked by the same grasp and breadth of treatment.

But perhaps the paper which has chiefly contributed to give Mr. Godwin-Austen his ascendency among English geologists and to make his name known beyond geological circles is his now well-known essay "On the Possible Extension of the Coal-Measures beneath the South-Eastern Part of England" (1855). In this remarkable memoir he brings to bear his detailed knowledge of the rocks of the south-west of England, the north of France, and the adjoining tracts of Belgium. He marshals all his facts in such a way as to enable us, as it were, to strip off the thick cover of Mesozoic formations and trace the deep-seated connection of the Palæozoic area of Southern England and the Continent. At the time when he wrote, nothing was actually known of the subject, but he predicted that a submerged Palæozoic ridge would be found extending from the south-west of England into France and Belgium. The results of the deep borings of recent years have fully verified this prediction.

Mr. Godwin-Austen, in his prime, was a frequent speaker at the meetings of the Geological Society, where his keen penetrative criticism and caustic sarcasm formed a prominent and valuable feature in the debates. Some of his most suggestive and pregnant views of geological questions were thrown off in the course of these debates, and were never otherwise published by him. He never courted publicity, but rather shrank from it as an incumbrance under which he would not willingly be fettered. For many years past he has lived as a retired country squire at his beautiful residence near Guildford, taking full interest in the progress of science, and glad to see his fellow-workers in geology under his roof, but seldom venturing into the turmoil of town and the disputatious atmosphere of learned societies. It is some consolation to geologists, who mourn the quenching of one of their luminaries, that his place is taken by a son who, by scientific labours in India and in this country, has proved himself a worthy successor.

CHARLES CLOUSTON

THE Rev. Chas. Clouston, LL.D., of Sandwick Manse, near Stromness, who died on the 10th ult. at the very advanced age of eighty-four years, was a man who

deserves more than a passing notice in our columns. To name one only of his many claims to scientific recognition, he commenced meteorological observations in Stromness in the year 1822, and continued them, either there or in the adjacent parish of Sandwick, to within a fortnight of his death in 1884.

He belonged to the old Norse stock in Orkney, coming from the township of Clouston in Stennis. Two families of this name now live in the township, having succeeded to their farms, by direct descent, for over 400 years. He studied in Edinburgh University, and had at first been destined for the medical profession. He became a Licentiate of the R.C.S. in Edinburgh in 1819, and at his death was probably the father of the College. When in 1826 he entered on his duties as assistant and successor to his father, in the combined parishes of Stromness and Sandwick, there was no medical man in the latter place. For nearly fifty years he acted as the local doctor, in addition to his clerical duties, giving advice and medicines *gratis*. His father had been minister of Stromness for over sixty years, so that father and son had kept up a continuous ministry for 120 years. He received the degree of LL.D. from the University of St. Andrew's many years ago.

In the year 1862 Dr. Clouston's reputation as a careful meteorological observer was so well established that Admiral FitzRoy intrusted to his charge an anemometer, which has been kept in constant operation for the space of twenty-two years. The original instrument was replaced by a new one in 1869. A discussion of the results of the first five years' records (1863-68) appeared in the *Quarterly Weather Report* for 1871. In addition to his regular observations and deductions therefrom, which he occasionally published, he wrote an essay, "An Explanation of the Popular Weather Prognostics of Scotland, on Scientific Principles," which gained the prize allotted by the Marquis of Tweeddale in 1867. His observations for the last thirty years, at least, have been regularly published by the Registrar-General for Scotland.

Dr. Clouston was not only a meteorologist, but an ardent follower of every branch of science which came in his way. In his "Guide to the Orkney Islands," a reprint of a portion of "Anderson's Guide," he modestly says, "Taking the Orkney Flora, as Dr. Neill left it, to include 462 specimens, and adding our own contribution of 156, it now contains 618 species." In archæology he took an active part in the exploration of Maes How, and the House of Skaill, both of them within a walk of his home.

Dr. Clouston leaves a widow, two sons, and two daughters, but more than one member of his family passed away before him. In conclusion, we can only say that a visit to Sandwick was ever a rare treat; the warm hospitality of the manse, and the interest of the conversation carried on round the table, could not fail to leave an impression which will not easily wear away.

ON THE AUTUMNAL TINTS OF FOLIAGE

AFTER the fine display of autumnal tints which we have lately seen it may, I trust, be of interest to some of the readers of NATURE if I give an account of the chief conclusions to which I have been led by carefully studying the subject for many years.

As a general rule the colour of leaves in their normal condition depends on a variable mixture of two perfectly distinct green pigments and of at least four perfectly distinct yellow substances. The development of the autumnal tints is mainly due to the disappearance or change of the green constituents and to the production of highly-coloured pigments by the oxidisation of previously existing very pale or colourless substances. It is, in fact, due to a more or less complete loss of the vitality which previously counteracted these chemical changes, and the order in which the tints are developed can be easily explained, if we assume that the death of the leaves takes place somewhat gradually. The first visible effect of the reduced vitality is the change in the green pigments. In many cases they appear to be converted into colourless products, since the resulting bright yellow leaves differ from the normal green in the absence of chlorophyll, and merely contain the usual previously-existing yellow pigments. At the same time it is quite possible that an increased quantity of some of these yellow substances may be formed as a product during the change, but of this there is no positive proof. In the case of such trees as the alder, the chlorophyll does not thus disappear, but is changed by the presence of a weak acid into a very stable brownish-green product which resists further change. The production of bright yellows or dull browns thus clearly depends on whether the chlorophyll does or does not disappear before being modified by the action of acids, as may be verified experimentally by exposing suitable solutions to sunlight. It is, however, very clear that the manner in which it changes depends very much on the conditions of the case. Thus, if chlorophyll is exposed to sunlight dissolved in bisulphide of carbon, a reddish-coloured product is formed, and though this differs very greatly from the red pigment met with in many autumnal leaves, it seems probable that under some conditions the chlorophyll in leaves is changed by the action of light into a red substance. By taking green sorrel leaves and keeping them somewhat fresh by sticking the stalks into moist ground, I found that those exposed to the sun with the under side upwards turned to a bright red, whereas those kept in the shade did not develop any fine colouring. We may often see that partially broken leaves or twigs undergo this change when all other parts of the tree remain green, and this and various other facts lead me to conclude that the change of chlorophyll into a red product depends on a certain amount of reduced vitality as well as on little-understood conditions varying in different kinds of plants. Though I fully admit that there are some facts not easy to understand, yet on the whole it seems to me that these principles fairly well explain why certain leaves turn red in autumn. Slight frosts reduce their vitality in such a manner that the chlorophyll is changed by the action of the light into a red product. Thus, according to the character of the season and the nature of the plants, the first effect of the reduced vitality in the leaves is that the chlorophyll is removed so as to show their normal yellow colour, or is changed into a red pigment, or is altered into a comparatively stable dull brown green product. These are the three extreme changes, but in many cases intermediate mixed results give rise to such less perfect and well-marked tints as dirty yellows and reds.

The next series of changes is best studied in the case of those leaves which in the first instance turn to a bright yellow, and it appears to me that they depend mainly, if not entirely, on the production of deeply-coloured pigments by the oxidisation of tannic acid and other more or less colourless substances. The difference in the resulting tint seems to depend on the nature of these substances. Thus, for example, the tannic acid in the yellow oak leaves changes into a brown substance, whereas the quino-tannic acid in yellow beech leaves changes into the fine orange-brown colour which makes those trees so ornamental in autumn. On the contrary, the bright yellow poplar leaves rapidly pass to a dark dirty brown by the alteration of another constituent. Other kinds of leaves give rise to tints of an intermediate and less well-marked character. In many cases it is almost impossible to draw the line between the colour of this stage in the change and the final dark and dirty browns of dead and decaying leaves. For fine effect very much depends upon the production of each special tint in a fairly pure state, so as to show bright yellows, reds, and browns. This seems to be influenced by the character of the weather.

It is also, of course, important that the half-dead leaves should hang long on the trees, so as to develop their full colouring before being blown off by the wind.

Taking thus all the facts into consideration, it appears clear that all the bright and beautiful tints of autumn are merely the earliest stages of decomposition, and are due to the more or less considerable triumph of chemical forces over the weakened or destroyed vitality of the living plant. One cannot but feel that this is a very unpoetical way in which to regard the magnificent tints of a fine autumnal landscape, but it is no less true than that the coloured clouds of evening mark the departing day.

H. C. SORBY

A TORNADO PHOTOGRAPHED

I SEND you to-day a photograph of a genuine Dakotah cyclone, or, rather, tornado, which was taken by F. N. Robinson, Howard, Miner County, D.T., August 28, 1884. The storm passed twenty-two miles west of the city. It was first noticed at 4 o'clock p.m., moving in a south-easterly direction, remaining in sight over two hours; killing several people, and destroying all property in its course. I believe it to be unique as a portrait of this class of storms, and I have thought you might care to reproduce it for NATURE.

EDWARD S. HOLDEN

Washburn Observatory, University of Wisconsin, Madison, November 14

METEOROLOGY OF MAGDEBURG[1]

THE second report, just published, of the Meteorological Observatory of Magdeburg presents some special features of interest. The observations with the instruments in more general use are given in very convenient forms in detail and abstract.

Magdeburg was one of the first observatories to adopt the barograph of Dr. Sprung, which is certainly one of the best barographs we possess. After the purchase-cost of 40*l.*, the annual outlay in working it and preparing its curves of continuous registration for the lithographer is trifling. The curves are also of high value as accurate representations of the variations of atmospheric pressure. The whole of these curves are reproduced by Dr. Assmann in an elaborate series of lithographs, on which the inch of pressure is on a scale of four inches, and the twenty-four hours of the day extend over five inches and a half. By this large scale the minuter changes of pressure are represented with great distinctness, and their relations to changes of wind, cloud, and other weather conditions can be more clearly seen. Dr. Assmann draws attention to five of the small changes from August 27 to 30 as disturbances due to the Krakatoa eruption.

The hourly values have been taken from these curves, and the means for the months calculated and added to the report. From these means and those of the previous year, a first approximation to the diurnal oscillation of the barometer for this part of Europe is obtained. The result is peculiarly interesting from the transitions it shows in the hourly variations of the summer pressure as compared on the one hand with the variations which occur at the stations of the German Seewarte on the North and Baltic Seas, and on the other with those which occur at places more in the interior of the Continent. Unfortunately for the prosecution of several inquiries raised by these differences, hourly hygrometric observations are not available from any of these first-class meteorological observatories.

Another interesting feature are the twelve lithographs which represent the continuous registrations of the sunshine recorder, on the scale of 0·4 inch for each hour These lines, which show the sunshine and inferentially the state of the sky in respect of cloud, give valuable information regarding certain hygrometric states of the atmosphere. Hence, with the aid of these and the barometric curves, the influence on the diurnal curve of

[1] "Jahrbuch der Meteorologischen Beobachtungen der Wetterwerte der Magdeburgischen Zeitung." Herausgegeben von Dr. R. Assmann. Jahrgang II. 1883. (Magdeburg, 1884).

pressure of such widely-contrasted states of weather as continuous strong sunshine and continuous cloud may be investigated.

The direction and force of the wind for each hour of the year is given in full. As regards force, the results show for each month a minimum during the night, or, rather, early morning, and a maximum at noon or shortly thereafter. The extremes of difference occurred in December and June, the maximum being only one-fifth greater than the minimum in December, whereas in June the wind blew with more than double the velocity during the hours about noon than it did from 2 to 4 a.m. It may be remarked here that also in June the sunshine attained to the annual maximum. The relations of the hourly variations of wind direction and force to some of the more decided disturbances of the barometric curves are interesting and striking; and still more striking and important would have been the comparisons of the minute disturbances in the barometric curve with similar disturbances shown by continuous registrations of direction and velocity of wind.

The rest of the report is taken up with observations, either once or thrice a day, of the temperature of the soil at depths, in metres, of 5, 3, 1, 0·15, 0·05, and 0·00; daily observations with maximum and minimum thermometers under a thin covering of earth, exposed on bare soil, and immediately over short grass; daily observations with five maximum and five minimum thermometers at heights, in metres, above the ground, of 0·05, 0·20, 0·40, 0·60, 0·80, and 1·00; observations with the solar radiation thermometer at a height of 102 feet, and on the evaporation,—all indicative of the spirit of activity and research which happily characterises this Observatory.

ON A HYDRIFORM PHASE OF "LIMNOCODIUM SOWERBII"

It is now four years and a half since Mr. Sowerby first discovered the fresh-water jelly-fish in the tank at Regent's Park, and since that time no definite advance has been made towards clearing up the mystery of their life-history.

Prof. Lankester has continued to make observations and experiments of various kinds, in which I have assisted him, but we have hitherto had no opportunity of examining the tank after the withdrawal of the water. This year, however, Prof. Lankester arranged with Mr. Sowerby that we should be present at that operation. This took place on Thursday last. We collected a large quantity of the sediment and portions of the roots of various plants, and Prof. Lankester kindly placed the whole of this material in my hands for further investigation. I soon discovered upon some of the *Pontederia* roots numerous specimens of a minute organism which proved to be hydroid in nature, and evidently a phase in the life-history of *Limnocodium*.

Further particulars, including an account of its remarkable structure, and the possible theories as to its connection with the Medusiform person, I reserve till next week, when Prof. Lankester has kindly offered to communicate them for me to the Royal Society.

I may add that Mr. Sowerby has kindly made arrangements at the Botanic Gardens for keeping the *Pontederia* roots in water in the warm tank during the winter, and that, with Mr. Thiselton Dyer's kind permission, I have placed one of the roots in the Royal Gardens at Kew.

ALFRED GIBBS BOURNE

NOTES

THE Lords of the Committee of Council on Education have received information, through Her Majesty's Principal Secretary of State for Foreign Affairs, that Her Majesty's Consul at Antwerp has been appointed British Commissioner for the International Exhibition which is to be held at Antwerp next year, and that Mr. P. L. Simmonds has been appointed by the Executive Council of the Exhibition at Antwerp their Agent-General for Great Britain and Ireland. The Exhibition in question is a national undertaking under the immediate patronage of His Majesty the King of the Belgians and of the Belgian Government. The President of the Exhibition is H.R.H. the Count of Flanders, and the Vice-President the Minister of Agriculture, Industry, and Commerce. The office of the Agent-General is at 35, Queen Victoria Street, and communications from intending exhibitors should be addressed to him there.

A REMARK was made at the Royal Society dinner on Monday touching the rapidly increasing number of awards of Royal medals not only to Cambridge men, but to men at Cambridge. In connection with it we may refer our readers to an appreciative article in Tuesday's *Times* on Natural Science at that University, in which the immense progress made during the last twenty years is well brought out. The results which may follow from the growth of a Medical School, and of Girton and Newnham, are indicated. The article concludes with the statement that the new studies, for good or ill, have taken root firmly. "They have already exercised a strong depolarising effect upon the cherished traditions and practices of the older studies. Everything is looked at in a new light, from a scientific point of view; and nothing which cannot stand the scientific test is allowed to pass unchallenged. The outcome of all this can be but dimly foreseen."

AT the annual meeting of the Fellows of the Royal Society of Edinburgh, held on Monday, the 24th ult., the following were elected office-bearers for next year:—President: Thomas Stevenson, M.I.C.E.; Vice-Presidents: Rev. W. Lindsay Alexander, D.D., Robert Gray, A. Forbes Irvine of Drum, Edward Sang, LL.D., David Milne Home, John Murray; General Secretary: Prof. Tait; Secretaries to Ordinary Meetings: Prof. Turner, Prof. Crum Brown; Treasurer: Adam Gillies Smith, C.A.; Curator of Library and Museum: Alexander Buchan, M.A.; Councillors: Prof. Cossar Ewart, Prof. James Geikie, Rev. Dr. W. Robertson Smith, Stair Agnew, Prof. Douglas Maclagan, M.D., Hon. Lord Maclaren, Rev. Prof. Flint, D.D., Prof. T. R. Fraser, M.D., Prof. Chiene, J. Y. Buchanan, Prof. Chrystal, Prof. Dickson.

THE University of Edinburgh has just suffered a severe loss by the sudden death of its Principal, Sir Alexander Grant. Many men of science in all parts of the world, who attended the Tercentenary Celebration last April, will remember the prominent and successful part played by the Principal in that remarkable gathering. Full of fresh zeal from this recent triumph of the University, he only a month ago opened the winter session by giving an address to the students, and seemed likely for many years to keep his post and witness a still further increase of that unexampled prosperity which the University has enjoyed under his rule. But this was not to be. He was struck down by an apoplectic attack on Sunday last in his fifty-eighth year.

M. COCHERY, the French Minister of Postal Telegraphy, has ordered the employment of the pneumatic system, which has now been completed in Paris, for the conveyance of ordinary letters to the several railway stations after the closing hours of the different post-offices, the charge being fixed at three deniers for each letter. This is said to be a step preliminary to the carriage of letters, instead of postal cards, by the tubes at an accelerated rate.

WE have received from Messrs. De La Rue and Co. their Diaries—pocket and otherwise—for the ensuing year, and also a charming collection of Christmas cards. The former are as beautifully finished and as full of scientific information and data

as usual. Some of the new series of Christmas and New Year's cards have also a scientific side to them, as they refer to flowers and birds, form and colour being carefully studied, and perhaps even more carefully given than they are in many books of botany and natural history. The series which gives us the story of a fox hunt by monkeys on dogs contains some very masterly drawing.

MR. NEWALL has forwarded to us a sketch of the face of one of several watches which he designed and had made some years ago by Mr. D. Glasgow, of Myddleton Square, President of the Horological Institute. The "hours" are replaced by a large round dot, which is easily seen even on a dark night in the Observatory, and there is no need for figures or a double row of them to count up to 24 o'clock, as has been suggested.

WE have received vol. xx. of the *Transactions* of the Royal Society of Victoria, being a record of the work of the Society for last year. The longest paper in the number is one by Mr. Howitt, on the rocks of Noyang; two communications by Messrs. Blunt and Jamieson deal with the influence of light on bacteria, while Mr. Ralph discusses the occurrence of bacteria (bacilli) in living plants. In a paper on modern fireproof and watertight building materials, Mr. Behrendt refers specially to Trägerwellblech ("bearing corrugated iron plates") and asphalte. Mr. Ellery, the President of the Society, communicates notes on the recent red sunsets, which he attributes to the prevalence of vapour in the higher regions of the atmosphere; on the rainfall map recently issued by the Government of Victoria; and on the early history of telegraphy, the invention of which he attributes to Mr. Edward Davy, at one time of the Assay Office in Melbourne. Mr. MacGillivray gives the fifth and sixth instalments of his lists and descriptions of new or little-known Polyzoa. The remaining papers printed in the volume (although many more were read before the Society) are:—On the caves perforating marble deposits, Limestone Creek, by Mr. Stirling; incandescent lamps for surgical and microscopical purposes, by Mr. Joseph; electric lighting for mines, by the same author; notes on the dressing of tin ore, by Mr. Newberry; and notes on hydrology, by Mr. Steane.

A PROJECT which, if executed, would render the Paris Exhibition of 1889 for ever memorable, has been published by M. Eiffel, the French engineer, and is described in *La Nature*. It is to erect in the grounds of the Exhibition an iron tower 300 metres in height, that is, twice as high as the Great Pyramid, and more than twice the height of the Strasburg Cathedral; 160 metres he considers as the limit of height possible in a structure of which stone is the principal material, and hence iron is proposed. The base of the tower is of pyramidal shape, and is to be 70 metres high, and the superficial area at this height will be 5000 square metres; above this there are to be three other stages, or stories, in which will be rooms which it is proposed to use for various purposes, scientific and other. The towers of Notre Dame will be mere pygmies beside this colossal structure, and will not reach to its first floor. The projector points out that, in addition to its monumental character, the structure will be useful for strategical purposes in war time, on account of the vast range of view, for meteorological and astronomical observations, for at such a height the clearness of the air and the absence of fogs would render observations possible which cannot be made on the ground. The tower might also be used for the electric light. The whole exhibition and the surrounding neighbourhood might thus be lighted from a central point. Many scientific problems may, it is suggested, be investigated from the tower, such as the resistance of the air to different weights, certain laws of elasticity, the study of the compression of gas or vapours, of the oscillation of the pendulum. In shape it is to resemble an enormous lighthouse, gradually tapering from a wide base to the summit.

WE learn from *Science* that the Norwegian bark *Loveid*, recently arrived in Philadelphia, reports a very peculiar squall experienced October 18, in lat. 39° 49′ N., long. 69° 5′ W. During fine, clear weather, with a light breeze from the northwest, heavy banks of clouds of most threatening aspect suddenly appeared, driving in every direction. Almost immediately a heavy squall of wind and rain struck the vessel, the wind shifting quickly all around the compass. In the midst of this disturbance, which lasted about an hour, a single peal of thunder was heard, and simultaneously a bolt of lightning struck the foreroyal mast-head, and ran down the mast to the royal yard, which was almost destroyed. The lightning, which looked like a ball of fire, then ran out on the horn of the cross-trees, and "burst" with a loud report, scattering sparks all over the vessel. The barometer fell suddenly from 30 to 28·60, and then rose as rapidly, the weather becoming pleasant immediately afterwards. This is rather a peculiar squall, considering the locality and the season.

THE New York *Financial and Mining News* contains an account of the extraordinary effect of an explosion of a large quantity of nitro-glycerine in what appeared to be an extinct oil-well in the Pennsylvanian oil-fields. A careful examination of the soil in the shaft failed to reveal any trace of oil or gas, and at length, as a last resource, it was decided to try the effect of an explosion of a shell containing fifty quarts of this explosive. First a column of water rose eight or ten feet and then fell back; a few moments later the burnt glycerine, mud, and sand rushed up the derrick in a black stream, the blackness gradually changing to yellow. Then, with a roar, the gas burst forth in a cloud which for a moment hid the derrick from sight, and as it cleared away revealed a solid golden column half a foot in diameter shooting from the derrick floor eighty feet through the air, till it broke into fragments on the crown pulley and fell in showers of golden rain for many yards around. This column of oil continued for an hour rushing in a torrent into the air. The branches of the trees around were like huge yellow plumes, and a large stream ran down the hill to a road, where it nearly filled the space beneath a small bridge. In two hours the neighbouring flats were covered with a flood of oil, and the hillside looked as if a freshet had passed over it, while heavy clouds of gas hung low over the woods. Dams were built across the stream in order that the production might be calculated, but they were borne away almost as soon as erected. The people living near the flats fled to the hills; fires had to be extinguished in the district to prevent a conflagration. The outflow was estimated at 8000 barrels in twenty-four hours. Ultimately the stream was diverted into the banks, after much labour and some danger. It was noticed that all the wells in the neighbourhood declined as soon as the outflow here mentioned commenced, the gauges in some of them showing at the end of three days a fall to half their previous depth.

M. JAMIN, Perpetual Secretary of the Paris Academy of Sciences, has been elected a member of the Société française de Navigation aérienne. He will take his seat next Thursday, the 11th inst., and is to deliver a speech on the occasion. He is at present engaged in writing an exhaustive article on aërial direction, which will very shortly appear in the *Revue des deux Mondes*.

ON Saturday night Mr. H. M. Stanley, on leaving Berlin after attending the West African Conference, was entertained at a banquet by the Central Society for Commercial Geography. A peculiar feature of the banquet was an ethnological study in the shape of a group of mummers representing some races of Africa, presumably those of the Cameroon and Angra Pequena regions.

AN earthquake was felt on Sunday and Monday, November 23 and 24, near Briançon, in the valley of Queyras on the banks

of the Guil, a torrent discharging into the Durance, in the Department of the Hautes Alpes. Three days afterwards, on Thursday the 27th, a severe shock was felt at Grenoble, about 100 km. west-south-west from the Queyras valley. It lasted thirty seconds, passing in a direction from west to east. All the houses were shaken, but no injury is reported beyond the fright sustained by the inhabitants. The same night, almost at the same hour, six shocks were felt at Lyons, moving in the same direction; and commotions of a similar kind are announced from Turin and the sea-coast of Provence, at Cannes and Nice in particular.

WE regret to hear that M. Duprez de Lonce, the celebrated naval engineer and Member of the French Academy of Sciences, is dangerously ill, and that his life is almost despaired of.

WE regret to announce the death, at Paris, at the age of seventy-four, of M. Quet, a distinguished French mathematician, well known for his works in connection with capillarity, electricity, &c., most of which have appeared in the *Comptes Rendus* of the Paris Academy of Sciences.

M. W. DE FONVIELLE has published a pamphlet on "L'Aérostat dirigeable de Meudon," in which he endeavours to show that the reports current in the French Academy respecting the experiments in question are exaggerated, though at the same time he seeks to do justice to his distinguished countryman, who has twice succeeded in proving that by means of electricity the power of resistance may be imparted to balloons. He concludes by recommending that, the electric fluids having done their part, *la parole est à le vapeur.*

INTERESTING researches with so-called Paradise fish (*Macropus venustus*) were made at the Berlin Aquarium recently. The fish is a native of China, its body, only a few centimetres long, is of the brightest hues, and its bluish-green fins are so enormously large that the fish seems almost to succumb under their weight. It is easily kept, and breeds frequently in captivity; the temperature of the water it is kept in must, however, not be allowed to sink below 20° C.

ONE result of the recent expedition sent from Quetta under Sir Oriel Tanner to punish the inhabitants of the Zhob Valley is stated in a telegram from Calcutta to be a complete survey of the whole of that valley. It has been ascertained that the best road from the Gomul Pass to Candahar does not lie, as had been supposed, through the Zhob Valley, but through the valley of the Khwandar, and that the route is practicable for a large army.

DR. OTTO FINSCH left Sydney on September 10 by the steamer *Samoa*, *en route* for the Phœnix and Union Islands, where he intends staying for some time and making extensive ethnographical collections.

THE *Boletin* of the National Academy of Sciences in Cordova, Argentine Republic (Buenos Ayres, 1884), has a very long paper by Señor Ameghino on his geological and palæontological investigations in the province of Buenos Ayres. The only other paper is by Herr Doering, and deals with the sinking of artesian wells in the Argentine Republic.

THE Rev. Henry H. Higgins publishes in a separate form a paper on "Museums of Natural History," read before the Literary and Philosophical Society of Liverpool. After an experience of over a quarter of a century, during which he passed several times every week through museum rooms, the author calculates that out of a thousand visitors to the Liverpool Museum, ten to twenty were students, 780 interested observers, and 200 loungers.

MR. CHARLES C. SHERRINGTON, B.A. of Caius College, Cambridge, has been elected to the vacant George Henry Lewes Studentship.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. W. J. Bennett; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. Samuel Levi; an Ocelot (*Felis pardalis*) from America, presented by Mr. H. B. Whitmarsh; two King Parrakeets (*Aprosmictus scapulatus*) from New South Wales, presented by Mr. E. Meek; a Cheer Pheasant (*Phasianus wallichii* ♀) from North India, presented by Mr. E. Buck; a Pig-tailed Monkey (*Macacus nemestrinus* ♂) from Java, deposited; a Rufous-necked Weaver Bird (*Hyphantornis textor*) from West Africa, received in exchange; four Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

THE ROYAL SOCIETY ANNIVERSARY

THIS meeting took place on Monday last, the time-honoured date—St. Andrew's Day—falling on Sunday. In the regretted absence of the President, Prof. Huxley, who, the Fellows were rejoiced to learn, is rapidly recovering his health from his sojourn in Italy, the Treasurer, Mr. John Evans, occupied the chair and read the following address:—

The absence of our President from his post to-day must of necessity cast a certain amount of gloom over the proceedings at this our anniversary meeting, and, personally, I feel additional regret that it devolves upon me, as your Senior Vice-President and Treasurer, to be the unworthy occupant of the chair on the present occasion. My regret at the absence of the President is, however, in one respect tempered by a strong hope, in which I am sure that you will all fervently join, that the timely retirement from arduous work which has been enforced upon him by his medical advisers may produce those beneficial results which we all so cordially desire, and that we may ere long again see among us our accomplished and valued President in renewed health and strength.

I must, however, turn from the expression of our hopes for the future, to that of our regrets for the past, and for a short time dwell upon the mournful list of vacancies which the ever-active hand of death has caused in our ranks during the past twelve months. In one respect only can a topic of consolation be found in this list. It is that in extent it is less than that of last year, the total number of our deceased Fellows being only eighteen on the home list and two on the foreign list, while those numbers were twenty-one and two respectively at our last anniversary.

Both the foreign members whose loss we have on the present occasion to deplore were men of the highest distinction in chemical science. Both were residents at Paris, and both had Chairs in the French Academy, of which the one had been since 1868 one of the permanent secretaries. I cannot dwell upon the discoveries and the remarkable career of M. Jean Baptiste André Dumas, whose energy and perspicuity, even when past the limit of fourscore years, all those who of late have had the opportunity of being present at a meeting of the French Academy must have found reason to admire. An appreciative memoir of him by one of our own Fellows, who of all men living is perhaps the best qualified to judge of the value of his labours—Prof. Hofman—written while Dumas was still among us, will be found in the pages of our own *Proceedings* (vol. xxxviii. x.), and those of NATURE (vol. xxi. February 6, 1880). It will give some slight idea of the extent of time over which the labours of M. Dumas have extended if I mention that, so long ago as in 1843, he received the Copley Medal at our hands, at a time when his chemical and physiological researches had already extended over a period of twenty-two years. M. Dumas died at Cannes on April 11 last, and among the most touching of the speeches at his obsequies was that of M. Würtz, whose own decease took place on the 12th of the following month.

Although nearly twenty years younger than M. Dumas, M. Karl Adolph Würtz had for a long time been one of the most distinguished leaders of modern chemical science, especially in the department of organic chemistry, and his merits were recognised by this Society in 1864, when he was elected one of our foreign members, and again in 1881, when the Copley Medal was awarded to him.

Among our English Fellows was a contemporary of Würtz, who, like him, had been a pupil of the illustrious Liebig, but whose bent was more on the practical than on the theoretical

side of chemistry—I mean Dr. Angus Smith, whose official labours in favour of pure air and pure water combined both tact and zeal, and were productive of highly beneficial results.

One other chemist has been taken from among us, Mr. Henry Watts, the well-known editor of the "Dictionary of Chemistry," and of more than one issue of "Fownes's Manual."

Our other losses extend over various departments of science. In botany our ranks are thinned by the death of Dr. John Hutton Balfour, formerly Professor of Botany at Glasgow and the Emeritus Professor of that Chair in the University of Edinburgh; and of the veteran Mr. George Bentham, who had nearly completed his eighty-fourth year. During his long and varied experiences of life, botany was his constant pursuit and study; and some thirty years ago, after presenting his fine collections and library to the Royal Gardens at Kew, he devoted himself to labouring there on the Floras of Hong Kong and Australia, and in conjunction with Sir Joseph Hooker, on the "Genera Plantarum," until his health gave way in the spring of last year. The exceptional value of his botanical work was recognised by this Society in 1859, when a Royal Medal was awarded to him, and his regard for the Society has been testified by his making a bequest of 1000*l*. to our Scientific Relief Fund.

Among mathematicians we have lost Dr. Isaac Todhunter, whose educational treatises have for many years been recognised as standard works, and whose elaborate histories of different branches of mathematical science have earned for him a high reputation; and Mr. Charles W. Merrifield, who, in addition to achieving distinction by his educational works on arithmetic and mathematics, did much in the direction of the practical application of science, and at the Royal School of Naval Architecture and Marine Engineering successfully laboured in improving the stability and the sea-going powers of the British Navy.

Another distinguished mathematician whom we have within the last few weeks had the misfortune to lose, was the Rev. Richard Townsend, Professor of Natural Philosophy in the University of Dublin, whose labours in the more abstruse fields of geometrical speculation extended over a period of nearly forty years. Mr. James Rennie was also a votary of mathematical research.

Among practical men of science, the veteran Mr. Charles Manby, who for forty-five years had been Secretary or Honorary Secretary of the Institution of Civil Engineers, will deservedly take a high place.

The anatomical and physiological labours of Prof. Allen Thomson had extended over the longer term of fifty-four years, and few possessed the power of clearer exposition than he, while for acts of personal kindness there must be many besides myself who owe him a deep debt of gratitude.

Among others connected with the medical profession we miss the distinguished surgeon Mr. Cæsar Hawkins, Dr. Alexander Tweedie, and Sir Erasmus Wilson, whose name will long survive, not only in connection with dermatology and the Chair of Pathological Anatomy at Aberdeen, but with the Egyptian obelisk, known as Cleopatra's Needle, the presence of which in London is entirely due to his liberality.

In Mr. R. A. C. Godwin-Austen we have lost one who for nearly fifty years had ranked among the foremost of English geologists. His manifold observations will be recorded elsewhere, but as an instance of his critical powers, I may mention his now classical paper on the possible extension of the Coal Measures beneath the south-eastern part of England, read in 1855, his speculations in which as to the western extension of the axis of Artois, all recent deep borings within the Thames Basin have so fully substantiated.

In Dr. Wright we have lost an accomplished palæontologist whose knowledge of the fossil Echinodermata and Ammonitidæ was almost unrivalled.

The Duke of Buccleuch had for fifty years been one of our Fellows, and in 1867 occupied the position of President of the British Association; while Sir Bartle Frere, although an ethnologist and geographer, will probably be better known as an able and energetic public servant and administrator than as a man of science.

In common with the nation at large, we have to deplore the untimely and unexpected decease of another distinguished statesman, the late Postmaster-General, Mr. Fawcett. A man of rare mental powers, the effect upon him of the greatest of all physical deprivations, the loss of sight, was only to make him rise superior to his misfortune. As a student of political economy he attained a high reputation, and he turned his mastery of the subject to good account when he entered into the sphere of public life towards which his natural aspirations led him. His singleness and honesty of purpose, the inborn justice of his well-balanced mind, his devotion to the public good, and his invariable courtesy, endeared him alike to political friends and opponents; while to those who were brought into more immediate contact with him, his truly sympathetic nature, and the marvellous memory which preserved even minute details of former conversations, gave a charm to his intercourse which none who enjoyed it will ever forget.

As I have already observed, our losses on the home list, including one resignation of Fellowship and one removal from our list, are less than in many former years, being altogether 21 in number; we have, on the other hand, elected 16 Fellows, including one Privy Councillor. It would, however, appear that our numbers are gradually attaining to something like a state of equilibrium, and that if our elections continue to be limited as at present, the roll of the Society will remain at its present standard of about 470 Fellows. Looking at the recognised longevity of scientific men and the age at which many now achieve the distinction of being elected into the Society, it seems to me not improbable that our numbers will ere long show a tendency to increase rather than to diminish.

Of the *Philosophical Transactions* three parts, and of the *Proceedings* eleven numbers, have been published; while the number of papers received during the past year was 100, as compared with 103 in the previous year. Of these the most numerous have been in the departments of electricity and magnetism, though physics and mathematics, chemistry, mineralogy, anatomy, and physiology, botany, and morphology have all had their share.

It is hardly within my province to select any papers that we have published as being the most worthy of mention. The mere fact that they have appeared in the *Philosophical Transactions* is a sufficient voucher for their value. I may, however, call attention to the report of Captain Abney and Dr. Schuster, our Bakerian Lecturer for the present year, on the total solar eclipse of May 17, 1882, which is the outcome of an expedition towards which a grant of 350*l*. was made from our Donation Fund. Some of the results were mentioned by Mr. Spottiswoode in his Presidential Address of 1882, but the value of the details with regard to the corona, and the success which attended the efforts of the photographers, can only be estimated from an examination of the paper itself. The detailed results obtained by the photographers who accompanied the American expedition to Caroline Island in the South Pacific in order to observe the solar eclipse of May 5, 1883, have not yet been brought before the Society.

In respect to biological studies, our record of the past year, though it does not contain the announcement of any very startling results, gives evidence of fruitful activity along various lines of research.

In Botany, Mr. Gardiner has continued his observations on the important subject of the continuity of protoplasm in vegetable cells, which was referred to in the President's Address of last year; he has also brought forward some interesting results derived from an examination of the changes in the gland-cells of Dionæa, which serve still further to illustrate the identity of the fundamental physiological processes in plants and animals. Mr. Bower has dealt with the morphology of the leaf in certain plants, in a memoir both valuable in itself, and noteworthy because hitherto the study of abstract vegetable morphology has perhaps not obtained in this country the attention which it deserves, and which has been given to it in other countries, especially in Germany.

In Physiology two important papers have been presented on the difficult subject of the functions of the cerebral convolutions, one by Drs. Ferrier and Yeo, and the other by Prof. Schafer and Mr. Horsley. Both contain observations which demand careful consideration by all physiologists.

The results of the study of animal forms which is happily being carried on with great activity, I may say, all over the United Kingdom, are for various reasons principally recorded elsewhere than in the pages of the *Transactions* or *Proceedings* of this Society. Nevertheless, this subject has also been fairly represented at our meetings. Our distinguished and unwearied Fellow, Prof. W. Kitchen Parker, is still continuing his elaborate and valuable researches on the vertebrate skull; and during the past session the Society has had the pleasure of receiving several short papers, expounded in person by their author, from

a veteran in the study of animal morphology, whose first communication to the Society bears the date of 1832. I need hardly say I mean Sir Richard Owen.

A few words must be said with regard to the acquisitions made by our library and collections. Our gallery of portraits has, through the kind liberality of Dr. Wilson of Florence, received two important additions in the form of half-length original portraits of the distinguished mathematicians and philosophers, Leibnitz and Viviani, both of whom were Foreign Members of this Society. When we remember the warmth of feeling with which the rival claims of Newton and Leibnitz to the invention of Fluxions or the Differential Calculus were for many years discussed, and call to mind that the question occupied the attention of a Committee of this Society in 1712, which reported in favour of Newton's claims, we may rejoice that the heat of the controversy is long since over, and congratulate ourselves that the portraits of these rival intellectual giants now hang peacefully side by side on our walls. The portrait of Viviani, the great geometrician, the pupil of Galileo and the associate of Torricelli, and a contemporary of Newton and Leibnitz, finds also a fitting resting-place in our gallery.

Our portfolio of engraved and lithographic portraits of scientific men has been considerably augmented by liberal donations from the executors of our former President, the late Sir Edward Sabine, through Mr. R. H. Scott.

The Lalande Medal, which had been awarded by the French Academy to Sir Edward in 1826, and which, together with a Royal Gold Medal, was presented to the Scientific Relief Fund, was by the Council redeemed from the Fund, and will be preserved among our other medals as a memorial of one who for so long a period rendered important services to the Society. A bronze medal of our distinguished Fellow, Prof. Sylvester, has been presented to our collection by the Johns Hopkins University, at Baltimore.

The library itself has during the past year received by donations about 380 complete volumes, besides about 240 pamphlets, and more than 2400 parts of serials; 24 charts have also been presented to it.

With regard to our finances, I may venture to say, as your Treasurer, that I consider them to be in a satisfactory condition.

I must now turn to some of the subjects which, during the past year, have occupied the attention of the President and Council, and which in more than one instance have brought them into communication with Her Majesty's Government.

In July of last year a letter from the Treasury was received requesting our opinion as to the desirability of subsidising the Armagh Observatory, the income of which had been materially reduced, owing to recent legislation in Ireland. In reply to this an answer was sent pointing out the good work that had been done in the Observatory, and the exceptional character of the institution, and recommending it to the favourable consideration of the Government. Unfortunately, however, the loss of income applicable to the maintenance of an Observatory has not been made good, though the Treasury, "having regard to the advice of the Royal Society, and to the diminution in the income of the Observatory," has granted a sum of 2,000*l*. in aid of its funds, the annual income derived from which sum is to be applied by trustees to the maintenance and purchase of instruments and apparatus.

Another correspondence with the Treasury as to the bathymetrical survey of the lakes within the British Isles did not lead to any concession in favour of such a necessary complement to the National Ordnance Survey, though the omission in our maps of all details relating to the depth of our lakes and the contour of their beds, cannot be justified on practical, and much less on scientific grounds.

In May last the Astronomer-Royal brought under our notice the position of this country with respect to the International Bureau des Poids et Mesures, an institution established by what is commonly known as the Metric Convention; and it was resolved that in the opinion of the President and Council it was highly desirable that our country should take part in the International Commission of Weights and Measures, and contribute the sum which our adhesion would entail. A deputation was appointed to bring the subject under the notice of the Lords of the Treasury, and, after some correspondence, the Society was authorised to enter into informal negotiations with the officers of the Bureau, with the happy result that Great Britain was invited to join the Metric Convention, and through her Ambassador at Paris has, I believe, now given in her adhesion to it, and is entitled to all the privileges accorded by the Bureau. The appliances at the command of the Bureau for the verification not only of the standards of the metric system, but of other units of measure, far surpass in scientific accuracy anything that is at present available in this country, and we now enjoy the double advantage of being removed from the state of isolation in which for some years we have stood in regard to the other nations of Europe, and of now being affiliated to an establishment in which the verification of standards has been carried to the highest perfection. At the same time, it is distinctly understood that our adhesion to the Bureau in no way commits the Government of this country to any change of opinion favourable to the adoption of the metric system, but that our entire freedom to retain our own system of weights and measures is absolutely preserved. Whatever may be the advantages of the metric system from a scientific point of view, the question whether a scale of weights, money, and measures, which in its lowest denominations follows a duodecimal rather than a decimal system, is not better adapted for the convenience of daily life, is one that by many is regarded as fairly open to discussion.

Another event of both scientific and national importance has been the meeting of an International Conference on the subject of a Prime Meridian of Longitude. The desirability of a common starting-point from which to reckon degrees of longitude has long been felt among all civilised nations, especially those of a maritime character, and was discussed at some length during the Congress of the International Geodetic Association at Rome in October 1883. It was not, however, until the end of last year that invitations were issued by the United States Government for different countries to send representatives to an International Conference to be held in the city of Washington for the purpose of discussing, and, if possible, fixing upon a meridian proper to be employed as a common zero of longitude and standard of time-reckoning throughout the globe. The letter of invitation addressed to this country was referred to the President and Council of this Society, with a request to advise the Government whether it was advisable in the interests of science to accept the invitation. In reply, an opinion was expressed as to the high importance, both for the interests of science in general, and of our own country in particular, that our Government should be represented at the Conference, and the Treasury at once sanctioned the expense of sending two delegates to Washington. These were Sir Frederick Evans, the late Hydrographer to the Admiralty, and Prof. J. C. Adams. General Strachey, the Chairman of the Meteorological Committee, was also nominated to represent India, and Mr. Fleming to represent the Dominion of Canada. The delegates assembled at Washington in the month of October last, and proceeded to discuss the questions whether a single prime meridian for all countries should be adopted, and if so, through what point on the earth's surface should that meridian be drawn. After long discussion it was eventually resolved that the meridian of Greenwich should be generally adopted, twenty-two[1] of the nations voting in favour of this measure, and only one, San Domingo, against it. The representatives of France and Brazil abstained from voting. The proposal for the adoption of Greenwich was made by one of the representatives of the United States of America, and was fully discussed. Our own representatives ably supported the proposal, and another of our most distinguished Fellows, Sir William Thomson, who happened to be in America at the time, was courteously invited to attend the meetings of the Conference, and on the request of the President to express his opinions. The arguments adduced in favour of the adoption of Greenwich were such as must commend themselves to all unprejudiced minds. It could hardly be expected that there should be any special spot upon the earth's surface from which longitude would naturally be reckoned, and the whole question, apart from any sentimental or patriotic feelings, is therefore one of the greatest convenience. Were the employment of degrees of longitude as general geographical units entirely unheard-of up to the present time, it would, of course, be a matter of perfect indifference whether the datum was at Greenwich, Paris, the Ferroe Isles, or any other spot. The meridians most in use are those of the two former places, and when we come to consider that, as was pointed out, the shipping tonnage controlled by the Greenwich

[1] The following nations voted in favour of Greenwich:—Austria, Chili, Colombia, Costa Rica, Great Britain, Guatemala, Hawaii, Italy, Japan, Liberia, Mexico, Netherlands, Paraguay, Russia, Salvador, Spain, Sweden, Switzerland, Turkey, United States, and Venezuela.

standard of longitude is about 14,000,000 tons, while that controlled by the longitude of Paris amounts to 1,750,000 tons only, the preponderance of convenience in favour of the former is placed beyond all dispute. The use of nautical charts constructed from the meridian of Greenwich, and also of the Greenwich *Nautical Almanac*, is by no means confined to the British Navy, for numerous other nations have availed themselves of the long-extended labours of our hydrographers, and the computations of our astronomers. At the same time there is no one among us who would for a moment venture to dispute the vast services to science which have been rendered by French astronomers and geographers, nor should we contest the right of French *savants* to regard Paris as the *μεσόμφαλος ἑστία* of all other branches of science; the question of a common zero of longitude, however, is not only of scientific but of commercial importance, and we may be confident that eventually our friends on the other side of the Channel, whose metric system has been so largely adopted by other countries, will in their turn sacrifice their own meridian, and adopt that which all neighbouring countries have declared to be the most convenient for general use. If some French locality on the meridian of Greenwich, such for instance as Argentan, were nominally the French datum, the results would be the same so far as maps and charts are concerned, and the natural patriotism of the French nation would remain uninjured.

The adoption of a universal day has also been recommended by the Conference. It is to be a mean solar day to begin for all the world at the moment of mean midnight of the initial meridian, coinciding with the beginning of the civil day and date of that meridian, and is to be counted from zero up to twenty-four hours.

The great volcanic eruption of Krakatoa, in the Straits of Sunda, which took place in August of last year, was followed by remarkable atmospheric and other disturbances, observations on which have been communicated to this and various other learned Societies, and have led to much interesting discussion. The fact, as pointed out by General Strachey and Mr. Scott, that at some barometrical stations the atmospheric wave caused by the eruption was still to be traced until about 122 hours after its origin, and that it must have travelled more than three times round the entire circuit of the earth, shows how vast must have been the initial disturbance causing the wave. The possibility of the remarkable atmospheric appearances which so constantly accompanied the rising and setting of the sun for some months subsequent to the eruption being due to volcanic dust in suspension in the air, offered a farther incentive to investigate the whole history of the eruption. In consequence, the Council in January last nominated a Committee to collect the various accounts of the volcanic eruption at Krakatoa and attendant phenomena, in such form as shall best provide for their preservation and promote their usefulness, and a sum of 100*l.* in all has been granted from the Donation Fund to defray the expenses of the Committee. A Committee of the Royal Meteorological Society, which had already been appointed to study the sunset phenomena of 1883-84, joined forces with our Committee, and their united labours, with Mr. A. Ramsay as secretary, have resulted in the accumulation of a voluminous mass of material. The accounts given in the chief British and foreign scientific serials have been extracted and classified, and the times of the various observations reduced to Greenwich mean time.

The literature on the subject, as Mr. Symons informs me, seems almost inexhaustible, and the Committee, feeling that some limit must be adopted, have now stopped the collection of further data, and are engaged in the discussion of what have already been obtained. The manuscript is classified according to subjects, and each of these is being studied by the members of the Committee most familiar with it. It is to be hoped that in the ensuing session we shall be favoured with some of the results of their labours.

In the Presidential Address of last year mention was made of a series of borings which it was proposed to make across the delta of the Nile in Egypt, and which, with the sanction of the Secretary of State for War, had been intrusted to the officer commanding the Royal Engineers attached to the army of occupation in Egypt. Shortly afterwards a Report from Col. Heriot Maitland, R.E., and Major R. H. Williams, R.E., was received, giving an account of a boring at Kasr-el-Nil, near Cairo, which had been carried to a depth of 45 feet, and of a second boring at Kafr Zaiyat, where a depth of 84 feet was attained. In both cases great difficulties had to be surmounted, but in neither was the solid rock reached beneath the superficial deposits. A second Report from the same officers, dated January 18 last, states that a third boring had been executed at Tantah, this time by the sappers of the Royal Engineers, and not by Arab workmen, though still with but imperfect tools. In this instance a depth of 73 feet was reached, but again without finding the solid rock. Samples of the materials obtained at different depths in these three borings have been forwarded to the Society by the War Department, and Prof. Judd has kindly undertaken their microscopic examination, and will shortly report the results of his labours to the Committee in charge of the subject.

With regard to the continuance of the borings, which seem to promise information of great value and interest, it is to be feared that the attention of the military authorities will for some time to come be attracted to more urgent business, though the Council of this Society has expressed its willingness to grant from the Donation Fund a further sum of 200*l.*, with the view of obtaining better apparatus for boring than that which has hitherto been employed.

The publication of the results of the *Challenger* Expedition, with which a Committee of this Society is to some extent concerned, has made considerable progress during the past year. Mr. Murray informs me that 47 Reports, forming 13 large quarto volumes, with 6276 pages of letterpress, 1051 lithographic plates, many woodcuts, charts, and other illustrations, have now been published. Nine other Reports are now being printed, and the eleventh Zoological volume and the first Botanical volume will be issued during the present financial year.

The work connected with the remaining thirty-six memoirs is making satisfactory progress, a large instalment of the manuscript being already prepared, and many of the plates either already printed off or drawn on the stone.

There has been an unavoidable delay in the case of the two volumes containing the narrative of the cruise and a general account of the scientific results of the Expedition, but it is expected that they will be issued within the next three months, and possibly before the end of the current year.

It was estimated that the investigations connected with the collections and observations made during the Expedition would be completed and published in 1887, and Mr. Murray has every reason to believe that the work will be finished within the estimated time.

The tenth Zoological volume which has just been issued, contains important Reports on the Nudibranchiata, Myzostomida, and Cirripedia, by Drs. Rudolph Bergh, L. von Graff, P. P. C. Hoek, as well as on the Cheilostomata, a sub-order of the Polyzoa, by Mr. George Busk. A first instalment of the Anthropological Report is also given by Prof. William Turner, in a detailed examination of the human crania, upwards of 60 in number, brought home by the Expedition. The total number of crania, however, described and tabulated in the memoir is 143, the whole from aboriginal and as yet uncivilised people. The previous Zoological volume is devoted to an exhaustive examination of the Foraminifera, by Mr. H. B. Brady.

The subject of the International Polar Observations, which were carried out during the twelve months ending with August 1883, has been touched on in recent Presidential Addresses, and in that for 1881 the general outline of the whole scheme was indicated. Now, however, the programme then only sketched out has been more than fulfilled, no less than 14 stations for observers, 12 for the Northern and 2 for the Southern Hemisphere, having been organised. Of all the expeditions, one only, that from Holland, failed to reach its destination, Dickson Harbour, at the mouth of the Obi River, as it was beset by ice in the Kara Sea, in the month of September 1882. The ship which carried the members of the expedition sank in the month of July 1883, but they all reached home in safety, having carried out their observations as fully as lay in their power. One of the two expeditions sent out by the Chief Signal Office, Washington, was not so fortunate. The party under Lieutenant Greely, after spending over two years at Lady Franklin Bay, Smith's Sound, was eventually rescued at Cape Sabine, in July last, but not before many of its members had succumbed beneath the fearful hardships of their protracted Arctic sojourn.

The actual points of observation, going eastwards from Behring Straits, and the States which sent out the expeditions, are tabulated below: —

Point Barrow	The United States.
Fort Rae	Great Britain and Canada.

Lady Franklin Bay	The United States.
Cumberland Sound.........	Germany.
Godthaab	Denmark.
Jan Mayen	Austria.
Spitzbergen	Sweden.
Bossekop	Norway.
Sodankyla	Finland.
Nova Zemlya	Russia.
Mouth of the Lena ...	Russia.
The Kara Sea	Holland.
In the Southern Hemisphere—	
Cape Horn	France.
South Georgia..	Germany.

At all of these stations observations were carried on for a year, and at some for even a longer period.

In the month of April last a Conference was held at Vienna, to decide as to the form and mode of discussion and publication of the results, and it may be hoped that these will appear before the end of 1885.

Of the serial publication, "Communications from the International Polar Commission," six parts, with an aggregate of 334 pages, have already appeared, and in it will be found all particulars of the undertaking.

The regulations under which the Government Grant of 4000*l.* is administered have during the past year been again under discussion, and have in some respects been slightly modified. It is, of course, needless to repeat that this grant, though nominally made to the Royal Society, in no way adds to its funds, while its administration rests with a Committee of from sixty or seventy members, many of whom are not of necessity Fellows of our Society. As the grant is now made in two instalments, it has been arranged that the meetings of the Committee shall be held twice in each year, viz., in May and December, which it is hoped will amply meet the convenience of applicants for grants.

In looking back upon the grants which have been made during the past year, I think that a tendency may be observed on the part of the Committee to devote considerable sums in aid of extensive researches rather than to fritter away the money at their disposal in a series of small grants. They have, for instance, allotted the sum of 500*l.* towards the exploration of Kilimanjaro and the adjoining mountains of Tropical Africa, and 200*l.* in aid of an expedition for the exploration of the mountain of Roraima in British Guiana. A grant of 200*l.* has also been made towards a report on the Flora of China; while 300*l.* has been allotted towards the extra accommodation and instruments for magnetic observations in the new Observatory of the Royal Cornwall Polytechnic Society. It will be remembered that, in his Address last year, the President called attention to the discovery by Dr. Huggins of a method of photographing the solar corona without an eclipse; and, for the purpose of making further experiments in this direction, and for carrying on other physical observations at some place of high elevation and of easy access, a grant of 250*l.* was placed at the disposal of a Committee. The place of observation selected by the Committee was the Riffel, near Zermatt, in Switzerland, which has an elevation of 8500 feet, and possesses important advantages both of access, and of hotel accommodation. They appointed Mr. C. Ray Woods, who had had experience in photographing the corona during the eclipse of 1882 in Egypt, and again in Caroline Island in 1883, to take charge of the work under the instructions of Dr. Huggins and Capt. Abney.

Mr. Woods arrived at the Riffel in the beginning of July, when he erected the necessary instruments under a tent of "Willesdenised" paper, and continued at work there until September 21. Unfortunately, the present year has been exceptionally unfavourable for work on the corona, in consequence of an unusual want of transparency in the higher regions of the atmosphere. This probably may be owing to the presence there of ice-crystals or of small particles of matter of some kind, such as, personally, I am tempted to think might be due to the Krakatoa eruption. Whatever the cause, the sky as seen from the Riffel was far from being so clear as it has been during former years. Mr. Woods observed that the freer the lower air was from cloud and mist, the more distinctly came out a great aureola around the sun, which he found to have a diameter of about 44°, and to be of a faint red near the outer boundary, and bluish-white within, up to the sun's limb.

These unfavourable conditions of the atmosphere have made it impossible for Dr. Huggins to obtain any photographs of the corona in England. The great advantage at the Riffel of being free from the light scattered from the lower 8000 feet of air has enabled Mr. Woods, notwithstanding the serious drawback of the persistent aureola, to obtain about 150 photographs, of which more than half are sufficiently good to show the general form, and a smaller number the stronger details of that part of the corona which lies within from 8′ to 12′ of the sun's limb. It would be premature to express any opinion as to the information which may eventually come out from the Riffel plates. They are now being drawn preparatory to a full discussion. In the meantime I may congratulate the Society upon the confirmation of the hope expressed by our President at the last anniversary, "that a new and powerful method of investigation has been placed in the hands of students of solar physics."

Another of the grants made by the Committee has also contributed to important scientific results, as it has enabled Mr. Caldwell to make some important observations on the early stages of the Monotreme ovum, a brief account of which was communicated to the meeting of the British Association for the Advancement of Science at Montreal. A fuller account of the observations, such as is necessary for the adequate appreciation of their importance and bearings, will, I hope, be laid before the Society during the ensuing session, when we shall also probably hear the result of similar investigations in like manner rendered possible by the existence of the Government Grant.

Some slight aid has been rendered from the same source towards the reduction of observations carried on at the meteorological station on the summit of Ben Nevis. This Observatory, situated on the highest point within the United Kingdom, has through the past year been under the charge of Mr. R. T. Omond and two assistants. During the summer months the buildings of the Observatory have been enlarged by the addition of new observing-rooms and increased accommodation for the observers and any scientific workers who may desire to carry on those physical researches for which the climate and position of Ben Nevis afford many facilities.

The erection and equipment of the Observatory have cost more than 5000*l.*; and, in connection with the observations carried on at the top of the mountain, others have been daily made near the sea-level at Fort William. A first report on these conjoint high- and low-level observations, which began in 1881, has been prepared by Mr. Buchan ("*Journal* of the Scottish Meteorol. Soc.," 3rd Series, No. 1 (1884), p. 4). The monthly normals for atmospheric pressure and temperature have been approximately determined for the Observatory. Important results have also been obtained relating to the decrement of temperature with height, for different months of the year and hours of the day, the diurnal variations of the wind's velocity, the very large increase in the rainfall on and near the summit, and the altogether unexpected hygrometric conditions of the air in their relation to the cyclones and anticyclones of North-Western Europe.

Another of the funds at our disposal, the Scientific Relief Fund, requires a few words of mention. Its resources have been considerably enriched during the past year by the legacy of 1000*l.* from Sir William Siemens, and nearly 50*l.* from the medals offered by the executors of the late Lady Sabine; and the legacy of 1000*l.* from the late Mr. Bentham will, it is hoped, ere long be received; but even with these munificent additions the income of the fund will amount to only 250*l.* per annum, while last year the calls upon it amounted, I regret to say, to no less than 450*l.* The incalculable value of such a fund to men of science or their families requiring temporary aid must be apparent to all, and looking at the unfortunate necessity for its existence which the calls upon it prove, I venture to commend it to your support. It will, perhaps, not be out of place here to say a few words with regard to the administration of this fund, the existence of which dates from 1859, and is in a great degree due to the exertions of the late Mr. Gassiot. The Council of the Royal Society takes charge of any sums contributed to the fund and invests them, applying the interest in grants for the relief of such scientific men or their families as may from time to time require or deserve assistance. These grants are, however, made only on the recommendation of a committee of seven members who investigate the cases before them, and applications for relief cannot be entertained except on the recommendation of the President of one of the chartered Societies, viz., the Astronomical, Chemical, Geographical, Geological, Linnean, Royal, and Zoological Societies. Since January 1861, when the first grant was made, the total number of grants has been eighty-eight, and the total sum distributed 4340*l.*

Our Donation Fund has also proved of much service, and several of the applications for comparatively small amounts, which were referred by the Government Grant Committee for the consideration of the Council of the Royal Society, were met by grants from this source. This most valuable fund, the annual income of which is now about 400*l*., has, during the past year, rendered important aid to various scientific objects. From it considerable grants have been made towards obtaining specimens of Hatteria and Apteryx; for expenses incurred on account of the voyage and investigations of the surveying-ship *Triton*; for collection of materials relating to the Krakatoa eruption; towards the borings in the Delta of Egypt; and, lastly, in aid of the Marine Biological Association.

The close connection of the future of our fisheries with the advancement of certain branches of zoological science was commented upon by our President in his last Anniversary Address, and I have now to record the foundation of two establishments devoted to marine research. The first of these is the station established at Granton, near Edinburgh, mainly through the energetic labours of Mr. John Murray of the *Challenger* Expedition. It consists of a floating laboratory where physical and biological investigations are carried on, and it is provided with a steam yacht for taking observations at sea and procuring specimens for examination. Chemical and other laboratories are now being erected on the shore, close to the inclosed piece of water where the floating laboratory is moored. Two naturalists, a chemist and a botanist, are permanently attached to the station, and have an engineer, a fisherman, and three attendants to assist them in conducting regular systematic observations. 2500*l*. have been spent on the equipment of the station, and it has at present an income of 400*l*. a-year, independent of the grants which some of the permanent staff have received from the Government Grant Committee to aid them in their researches. It is well that it should be known that any scientific observer is at liberty to make use of the station free of charge; indeed, during the past year five gentlemen and one lady have availed themselves of this privilege during short periods of time.

But the movement in favour of such stations has not been confined to Scotland, for I have also to chronicle the foundation of the Marine Biological Association, which originated in a meeting held in these rooms on March 31 last, our President being in the chair, and many of our principal naturalists taking part in the proceedings. The formation of such an Association has long been hoped for by many interested in obtaining a correct knowlege of the life and conditions of our sea-coast, who are now principally indebted to Prof. Ray Lankester for the realisation of their hopes. The operations of the Association will in no way clash with those of the station at Granton, but both institutions will work towards a common end. One effect, indeed, of the new Association will probably be to render all the more fruitful the labours on the more northern shores by instituting similar researches at other parts of the coast of our island.

The work of the Association is as yet in the inceptive stage, but a site well adapted for a marine observatory will, through the liberal endeavours of the Mayor and Corporation of Plymouth, probably be secured in that town, some citizens of which have also promised a noble donation of 1000*l*. towards its erection. The Clothworkers' Company has contributed 500*l*. and the Mercers' Company 250 guineas, while the Council of this Society has also shown its sympathy with the movement by a grant of 250*l*., and the British Association by one of 150*l*. Handsome donations have also been made by private individuals, and the number of members of the Association is gradually increasing. When once the station is completed and at work, and its aims and operations become better known, I make little doubt that it will receive a much larger share of public support. But before the station can be erected and at work, it is calculated that an outlay of 10,000*l*. is necessary for its building and equipment, of which as yet not quite half is forthcoming, and I venture to take this opportunity of enforcing the claims of the Association upon all who are interested in "the improvement of natural knowledge." As has already been pointed out in the memorandum issued by the Association, "great scientific and practical results have been obtained in other countries, notably in the United States of America, in Germany, France, and Italy, by studies carried on through such laboratories as the Marine Biological Association proposes to erect in this country," and I may add as is already at work at Granton. When we consider the enormous importance of our fisheries, and how large may be the amount of material benefit derived from a scientific investigation of the causes of their increase and diminution, it will, I think, be evident that the work to be carried on at these stations is not only for such a purpose as the development of abstract biological science, important as that may be, but for the advancement of our national resources. It is, therefore, to be hoped that, in addition to the private support which they will receive, they may in some manner be recognised by the nation at large as centres for carrying out systematic investigations into the circumstances determining marine life, from which a portion of our food-supply is drawn, and a much larger portion might probably be derived. The importance of our sea fisheries, which it will be one of the principal objects of the Association to promote, has of late years been more fully recognised, and the recent International Fisheries Exhibition has done much to popularise the subject; while the official appointment of our President also proves that in the opinion of our Government the scientific aspects of our fisheries are not to be neglected.

In the last Presidential Address reference was made to the great desirability of carrying out, on the part of this country, investigations into the nature of cholera in continuation and extension of those so zealously and bravely initiated by the distinguished German inquirer Koch. Although the Society has had no very direct influence in the matter, the Fellows will, I venture to think, regard it as a subject for congratulation that the wish then expressed from this chair has been fulfilled, and that the distinguished expert in such questions—our Fellow, Dr. Klein—is at present engaged in India in the investigation of cholera at the instance of the Indian Government. It is sad to think how much nearer our own shores such investigations might have been conducted; may it be long ere they can be instituted on this side of the Channel.

These remarks have already extended to such a length that I can now only briefly refer to a few of the events of scientific interest which have during the past year occupied the attention of the Society or of a large number of its Fellows. In the month of April last the University of Edinburgh celebrated its Tercentenary with great pomp and no less hospitality, upwards of 120 delegates from various universities and other learned bodies being invited as guests. On this occasion Lord Rayleigh kindly consented to be our representative, and was among those on whom the University conferred the honorary degree of LL.D. The same distinguished Fellow occupied the Presidential chair at the meeting of the British Association for the Advancement of Science at Montreal, on which occasion many of our body took the opportunity of crossing the Atlantic. Owing to the munificent liberality and ungrudging hospitality of our brethren in the Dominion of Canada, the somewhat bold experiment of holding a meeting of the Association beyond the limits of the British Isles has proved a great success, though, perhaps, it is an experiment which would require exceptional conditions to be successfully repeated.

The Society was represented by delegates at the meeting of the American Association for the Advancement of Science at Philadelphia in September last. The Electrical Exhibition at the same place resulted in the formation of a Memorial Library in connection with the Franklin Institute, to which separate copies of the papers relating to electricity that have appeared in the *Philosophical Transactions* have been granted by the Council. An Electrical Congress at Paris, and an Ornithological one at Vienna have also been among the events of the year.

Subscribers to the Darwin Memorial Fund will be pleased to hear that a fine block of marble has been secured for the statue to be erected in the Natural History Museum at South Kensington, and I am glad to learn from Mr. Boehm that his work will probably be completed by the end of this year. When the total cost of the statue has been ascertained, it will be necessary to hold a meeting of the Committee in charge of the Memorial Fund to determine the manner in which the balance is to be applied.

It now only remains for me to thank the Fellows and others conversant with the subjects on which I have touched, for information kindly afforded me; to thank you for the attention with which you have listened to me, and to express a hope that it may not again for many years occur that the Anniversary Address from this Presidential chair shall have to be delivered by deputy.

After the Address the awards of the medals and the election of the Council for the ensuing year were proceeded with; these we

have already referred to. A gloom was cast over the meeting by the announcement of the sudden death of Prof. Kolbe, the distinguished recipient of the Davy Medal.

The Annual Dinner subsequently took place at Willis's Rooms, the Treasurer being supported by the Lord Chancellor, the Marquess of Salisbury, the Lord Mayor, and others.

THE WAVE THEORY OF LIGHT[1]

II.

To continue our study of visible light, that is, undulations extending from red to violet in the spectrum (which I am going to show you presently), I would first point out on this chart that in the section from letter "A" to letter "D" we have visual effect and heating effect only; but no ordinary chemical or photographic effect. Photographers can leave their usual sensitive chemically prepared plates exposed to yellow light and red light without experiencing any sensible effect; but when you get

The Solar Spectrum.

toward the blue end of the spectrum the photographic effect begins to tell, more and more as you get towards the violet end. When you get beyond the violet, there is the invisible light known chiefly by its chemical action. From yellow to violet we have visual effect, heating effect, and chemical effect, all three; above the violet only chemical and heating effects, and so little of the heating effect that it is scarcely perceptible.

The prismatic spectrum is Newton's discovery of the composition of white light. White light consists of every variety of colour from red to violet. Here, now, we have Newton's prismatic spectrum produced by a prism. I will illustrate a little in regard to the nature of colour by putting something before the light which is like coloured glass; it is coloured gelatine. I will put in a plate of red gelatine which is carefully prepared of chemical materials, and see what that will do. Of all the light passing to it from violet to red it only lets through the red and orange, giving a mixed reddish colour.

Here is another plate of green gelatine. The green absorbs all the red, giving only green. Here is another plate absorbing something from each portion of the spectrum, taking away a great deal of the violet and giving a yellow or orange appearance to the light. Here is another absorbing out the green, leaving red, orange, and a very little faint green, and absorbing out all the violet.

When the spectrum is very carefully produced, far more perfectly than Newton knew how to show it, we have a homogeneous spectrum. It must be noticed that Newton did not understand what we call a homogeneous spectrum; he did not produce it, and does not point out in his writings the conditions for producing it. With an exceedingly fine line of light we can bring it out as in sunlight, like this upper picture, red, orange, yellow, green, blue, indigo, and violet, according to Newton's nomenclature. Newton never used a narrow beam of light, and so could not have had a homogeneous spectrum.

This is a diagram painted on glass and showing the colours as we know them. It would take two or three hours if I were to explain the subject of spectrum analysis to-night. We must tear ourselves away from it. I will just read out to you the wave lengths corresponding to the different positions in the sun's spectrum of certain dark lines commonly called "Fraunhofer's lines." I will take as a unit the one-hundred-thousandth of a centimetre. A centimetre is ·4 of an inch; it is a rather small half an inch. I take the thousandth of a centimetre and the hundredth of that as a unit. At the red end of the spectrum the light in the neighbourhood of that black line "*A*" has for its wave length 7·6; "*B*" has 6·87; "*D*" has 5·89; the "frequency" for "*A*" is 3·9 times 100 million million; the frequency of "*D*" light is 5·1 times 100 million million per second.

Now what force is concerned in those vibrations as compared with sound at the rate of 400 vibrations per second; suppose for a moment the same matter was to move to and fro through the same range, but 400 million million times per second. The force required is as the square of the number expressing the frequency. Double frequency would require quadruple force for the vibration of the same body. Suppose I vibrate my hand again, as I did before. If I move it once per second a moderate force is required; for it to vibrate ten times per second 100 times as much force is required; for 400 vibrations per second 160,000 times as much force.

If I move my hand once per second through a space of a quarter of an inch a very small force is required; it would require very considerable force to move it ten times a second, even through so small a range; but think of the force required to move a tuning fork 400 times a second; compare that with the force required for a motion of 400 million million times a second. If the mass moved is the same, and the range of motion is the same, then the force would be one million million million million times as great as the force required to move the prongs of the tuning fork. It is as easy to understand that number as any number like 2, 3, or 4.

Consider gravely what that number means and what we are to infer from it. What force is there in space between my eye and that light? What forces are there in space between our eyes and the sun, and our eyes and the remotest visible star? There is matter and there is motion, but what magnitude of force may there be?

I move through this "luminiferous ether" as if it were nothing. But were there vibrations with such frequency in a medium of steel or brass, they would be measured by millions and millions and millions of tons action on a square inch of matter. There are no such forces in our air. Comets make a disturbance in the air, and perhaps the luminiferous ether is split up by the motion of a comet through it. So when we explain the nature of electricity, we explain it by a motion of the luminiferous ether. We cannot say that it is electricity. What can this luminiferous ether be? It is something that the planets move through with the greatest ease. It permeates our air; it is nearly in the same condition, so far as our means of judging are concerned, in our air and in the inter-planetary space. The air disturbs it but little; you may reduce air by air-pumps to the hundred-thousandth of its density, and you make little effect in the transmission of light through it. The luminiferous ether is an elastic solid. The nearest analogy I can give you is this jelly which you see.[1] The nearest analogy to the waves of light is the motion, which you can imagine, of this elastic jelly, with a ball of wood floating in the middle of it. Look there, when with my hand I vibrate the little red ball up and down, or when I turn it quickly round the vertical diameter, alternately in opposite directions;—that is the nearest representation I can give you of the vibrations of luminiferous ether.

Another illustration is Scottish shoemaker's wax or Burgundy pitch, but I know Scottish shoemaker's wax better. It is heavier than water, and absolutely answers my purpose. I take a large slab of the wax, place it in a glass jar filled with water, place a number of corks on the lower side and bullets on the upper side. It is brittle like the Trinidad pitch or Burgundy pitch which I have in my hand. You can see how hard it is, but if left to itself it flows like a fluid. The shoemaker's wax breaks with a brittle fracture, but it is viscous and gradually yields.

What we know of the luminiferous ether is that it has the rigidity of a solid and gradually yields. Whether or not it is brittle and cracks we cannot yet tell, but I believe the discoveries in electricity, and the motions of comets, and the marvellous spurts of light from them, tend to show cracks in the luminiferous ether—show a correspondence between the electric flash and the aurora borealis and cracks in the luminiferous ether. Do not take this as an assertion, it is hardly more than a vague scientific dream: but you may regard the existence of the luminiferous ether as a reality of science, that is, we have an all-pervading medium, an elastic solid, with a great degree of rigidity; its rigidity is so prodigious in proportion to its density that the vibrations of light in it have the frequencies I have mentioned, with the wave lengths I have mentioned.

The fundamental question as to whether or not luminiferous ether has gravity has not been answered. We have no knowledge that the luminiferous ether is attracted by gravity; it is sometimes called imponderable because some people vainly imagine that it has no weight. I call it matter with the same kind of rigidity that this elastic jelly has.

[1] A Lecture delivered at the Academy of Music, Philadelphia, under the auspices of the Franklin Institute, September 29, 1884, by Sir William Thomson, F.R.S., LL.D. (Continued from p. 94).

[1] Exhibiting a large bowl of clear jelly with a small red wooden bal embedded in the surface near the centre.

Here are two tourmalines; if you look through them toward the light, you see the white light all round, *i.e.* they are transparent. If I turn round one of these tourmalines the light is extinguished, it is absolutely black, as though the tourmalines were opaque. This is an illustration of what is called polarisation of light. I cannot speak to you about qualities of light without speaking of the polarisation of light. I want to show you a most beautiful effect of polarising light, before illlustrating a little further by means of this large mechanical illustration which you have in the bowl of jelly. Now I put in the lantern another instrument called a "Nicol prism." What you saw first were two plates of the crystal tourmaline which came from Brazil, I believe, having the property of letting light pass when both plates are placed in one particular direction as regards their axes of crystallisation, and extinguishing it when it passes through the first plate held in another direction. We have now an instrument which also gives rays of polarised light. A Nicol prism is a piece of Iceland spar, cut in two and turned, one part relatively to the other, in a very ingenious way, and put together again and cemented into one by Canada balsam. The Nicol prism takes advantage of the property which the spar has of double refraction, and produces the phenomenon which I now show you.

I turn one prism round in a certain direction and you get light, a maximum of light. I turn it through a right angle and you get blackness. I turn it one quarter round again and get maximum light; one quarter more, maximum blackness; one quarter more and bright light. We rarely have such a grand specimen of a Nicol prism as this.

There is another way of producing polarised light. I stand before that light and look at its reflection in a plate of glass on the table through one of the Nicol prisms, which I turn round, so. Now I must incline that piece of glass at a particular angle, rather more than 45°; I find a particular angle in which, if I look at it and then turn the prism round in the hand, the effect is absolutely to extinguish the light in one position and to give it maximum brightness in another position. I use the term "absolute" somewhat rashly. It is only a reduction to a very small quantity of light, not an absolute annulment as we have in the case of the two Nicol prisms used conjointly. Those of you who have never heard of this before would not know what I am talking about. As to the mechanics of the thing it could only be explained to you by a course of lectures in physical optics. The thing is this, vibrations of light must be in a definite direction relatively to the line in which the light travels.

Look at this diagram, the light goes from left to right; we have vibrations perpendicular to the line of transmission. There is a line up and down which is the line of vibration. Imagine here a source of light, violet light, and here in front of it is the line of propagation. Sound vibrations are to and fro; this is transverse to the line of propagation. Here is another, perpendicular to the diagram, still following the law of transverse vibration; here is another circular vibration. Imagine a long rope, you whirl one end of it and you send a screw-like motion running along; you can get the circular motion in one direction or in the opposite.

Plane polarised light is light with the vibrations all in a single plane, perpendicular to the plane through the ray which is technically called the "plane of polarisation." Circular polarised light consists of undulations of luminiferous ether having a circular motion. Elliptically polarised light is something between the two, not in a straight line, and not in a circular line; the course of vibration is an ellipse. Polarised light is light that performs its motions continually in one mode or direction. If in a straight line it is plane polarised light; if in a circular direction it is circularly polarised light; when elliptical it is elliptically polarised light.

With Iceland spar, one unpolarised ray of light divides on entering it into two rays of polarised light, by reason of its power of double refraction, and the vibrations are perpendicular to one another in the two emerging rays. Light is always polarised when it is reflected from a plate of unsilvered glass, or water, at a certain definite angle of 56° degrees for glass, or 52° for water, the angle being reckoned in each case from a perpendicular to the surface. The angle for water is the angle whose tangent is 1·4. I wish you to look at the polarisation with your own eyes. Light from glass at 56° and from water at 52° goes away vibrating perpendicularly to the plane of incidence and plane of reflection.

We can distinguish it without the aid of an instrument. There is a phenomenon well known in physical optics as "Haidinger's Brushes." The discoverer is well known in Philadelphia as a mineralogist, and the phenomenon I speak of goes by his name. Look at the sky in a direction of 90° from the sun, and you will see a yellow and blue cross, with the yellow toward the sun, and from the sun, spreading out like two fox's tails with blue between, and then two red brushes in the space at right angles to the blue. If you do not see it, it is because your eyes are not sensitive enough, but a little training will give them the needed sensitiveness.

If you cannot see it in this way try another method. Look into a pail of water with a black bottom; or take a clear glass dish of water, rest it on a black cloth and look down at the surface of the water on a day with a white cloudy sky (if there is such a thing ever to be seen in Philadelphia). You will see the white sky reflected in the basin of water at an angle of about 50°. Look at it with the head tipped to one side and then again with the head tipped to the other side, keeping your eyes on the water, and you will see Haidinger's brushes. Do not do it fast or you will make yourself giddy. The explanation of this is the refreshing of the sensibility of the retina. The Haidinger's brush is always there, but you do not see it because your eye is not sensitive enough. After once seeing it you always see it; it does not thrust itself inconveniently before you when you do not want to see it. You can readily see it in a piece of glass with dark cloth below it, or in a basin of water.

I am going to conclude by telling you how we know the wave lengths of light and how we know the frequency of the vibrations. We shall actually make a measurement of the wave length of the yellow light. I am going to show you the diffraction spectrum.

You see on the screen,[1] on each side of a central white bar of light, a set of bars of light variegated colours, the first one, on each side, showing blue or indigo colour about four inches from the central white bar and red about four inches farther, with vivid green between the blue and the red. That effect is produced by a grating with 400 lines to the centimetre, engraved on glass, which I now hold in my hand. The next grating has 3000 lines on a Paris inch. You see the central space and on each side a large number of spectra, blue at one end and red at the other. The fact that, in the first spectrum red is about twice as far from the centre as the blue, proves that a wave length of red light is double that of blue light.

I will now show you the operation of measuring the length of a wave of sodium light, that is a light like that marked "*D*" on the spectrum, a light produced by a spirit lamp with salt in it. The sodium vapour is heated up to several thousand degrees, when it becomes self luminous and gives such a light as we get by throwing salt upon a spirit lamp in the game of snap-dragon.

I hold in my hand a beautiful grating of glass silvered by Liebig's process with metallic silver, a grating with 6480 lines to the inch, belonging to my friend Prof. Barker, which he has kindly brought here for us this evening. You will see the brilliancy of colour as I turn the light reflected from the grating toward you, and pass the beam round the room. You have now seen directly with your own eyes these brilliant colours reflected from the grating, and you have also seen them thrown upon the screen from a grating placed in the lantern. With a grating of 17,000 lines—a much greater number of lines per inch than the other—you will see how much further from the central bright space the first spectrum is; how much more this grating changes the direction or diffraction of the beam of light. Here is the centre of the grating, and there is the first spectrum You will note that the violet light is least diffracted and the red light is most diffracted. This diffraction of light first proved to us definitely the reality of the undulatory theory of light.

You ask why does not light go round a corner as sound does. Light does go round a corner in these diffraction spectra; it is shown going round a corner, it passes through these bars and is turned round an angle of 30°. Light going round a corner by instruments adapted to show the result, and to measure the angles at which it is turned, is called the diffraction of light.

I can show you an instrument which will measure the wave lengths of light. Without proving the formula, let me tell it to you. A spirit lamp with salt sprinkled on the wick gives very nearly homogeneous light, that is to say, light all of one wave length, or all of the same period. I have a little grating which I take in my hand. I look through this grating and see that

[1] Showing the chromatic bands thrown upon the screen from a diffraction grating.

candle before me. Close behind it you see a blackened slip of wood with two white marks on it ten inches asunder. The line on which they are marked is placed perpendicular to the line at which I shall go from it. When I look at this salted spirit lamp I see a series of spectra of yellow light. As I am somewhat short-sighted I am making my eye see with this eyeglass and the natural lenses of the eye what a long-sighted person would make out without an eyeglass. On that screen you saw a succession of spectra. I now look direct at the candle and what do I see? I see a succession of five or six brilliantly coloured spectra on each side of the candle. But when I look at the salted spirit lamp, now I see ten spectra on one side and ten on the other, each of which is a monochromatic band of light.

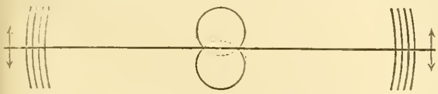
I will measure the wave lengths of light thus. I walk away to a considerable distance and look at the candle and marks. I see a set of spectra. The first white line is exactly behind the candle. I want the first spectrum to the right of that white line to fall exactly on the other white line, which is ten inches from the first. As I walk away from it I see it is now very near it; it is now on it. Now the distance from my eye is to be measured, and the problem is again to reduce feet to inches. The distance from the spectrum of the flame to my eye is thirty-four feet nine inches. Mr. President, how many inches is that? 417 inches, in round numbers 420 inches. Then we have the proportion, as 420 is to 10 so is the length from bar to bar of the grating to the wave length of sodium light. That is to say, as forty-two is to one. The distance from bar to bar is the four-hundredth of a centimetre: therefore the forty-second part of the four-hundredth of a centimetre is the required wave length, or the 16,800th of a centimetre is the wave length according to our simple, and easy, and hasty experiment. The true wave length of sodium light, according to the most accurate measurement, is about a 17,000th of a centimetre, which differs by scarcely more than 1 per cent. from our result!

The only apparatus you see is this little grating; it is a piece of glass with four-tenths of an inch ruled with 400 fine lines. Any of you who will take the trouble to buy one may measure the wave lengths of a candle flame himself. I hope some of you will be induced to make the experiment for yourselves.

If I put salt on the flame of a spirit lamp, what do I see through this grating? I see merely a sharply defined yellow light, constituting the spectrum of vaporised sodium, while from the candle flame I see an exquisitely coloured spectrum, far more beautiful than I showed you on the screen. I see in fact a series of spectrums on the two sides with the blue toward the candle flame, and the red further out. I cannot get one definite thing to measure from in the spectrum from the candle flame as I can with the flame of a spirit lamp with the salt thrown on it, which gives, as I have said, a simple yellow light. The highest blue light I see in the candle flame is now exactly on the line. Now measure to my eye, it is forty-four feet four inches, or 532 inches. The length of this wave then is the 532nd part of the four-hundredth of a centimetre, which would be the 21,280th of a centimetre, say the 21,000th of a centimetre. Then measure for the red, and you would find something like the 11,000th for the lowest of the red light.

Lastly, how do we know the frequency of vibration?

Why, by the velocity of light. How do we know that? We know it in a number of different ways, which I cannot explain now, because time forbids. Take the velocity of light. It is 187,000 British statute miles per second. But it is much better to take a kilometre for the unit. That is about six-tenths of a mile. The velocity is very accurately 300,000 kilometres per second; that is, 30,000,000,000 centimetres per second. Take the wave length as the 17,000th of a centimetre, and you find the frequency of the sodium light to be 510 million million per second. There, then, you find a calculation of the fre-



Vibrating spherule embedded in an elastic solid.

quency from a simple observation which you can all make for yourselves.

Lastly, I must tell you about the colour of the blue sky which was illustrated by the spherule embedded in an elastic solid. I want to explain to you in two minutes the mode of vibrations. Take the simplest plane polarised light. Here is a spherule which is producing it in an elastic solid. Imagine the solid to extend miles horizontally and miles down, and imagine this spherule to vibrate up and down. It is quite clear that it will make transverse vibrations similarly in all horizontal directions. The plane of polarisation is defined as a plane perpendicular to the line of vibration. Thus, light produced by a molecule vibrating up and down, as this red globe in the jelly before you, is polarised in a horizontal plane, because the vibrations are vertical.

Here is another mode of vibrations. Let me twist this spherule in the jelly as I am doing it, and that will produce vibrations, also spreading out equally in all horizontal directions. When I twist this globe round, it draws the jelly round with it; twist it rapidly back, and the jelly flies back. By the inertia of the jelly the vibrations spread in all directions, and the lines of vibration are horizontal all through the jelly. Everywhere, miles away, that solid is placed in vibration. You do not see it, but you must understand that they are there. If it flies back it makes vibration, and we have waves of horizontal vibrations travelling out in all directions from the exciting molecule.

I am now causing the red globe to vibrate to and fro horizontally. That will cause vibrations to be produced which will be parallel to the line of motion at all places of the plane perpendicular to the range of the exciting molecule. What makes the blue sky? These are exactly the motions that make the blue light of the sky, which is due to spherules in the luminiferous ether, but little modified by the air. Think of the sun near the horizon; think of the light of the sun streaming through and giving you the azure blue and violet overhead. Think first of any one particle of the sun, and think of it moving in such a way as to give horizontal and vertical vibrations and what not of circular and elliptic vibrations.

You see the blue sky in high-pressure steam blown into the air; you see it in the experiment of Tyndall's blue sky, in which a delicate condensation of vapour gives rise to exactly the azure blue of the sky.

Now the motion of the luminiferous ether relatively to the spherule gives rise to the same effect as would an opposite motion impressed upon the spherule quite independently by an independent force. So you may think of the blue colour coming from the sky as being produced by to-and-fro vibrations of matter in the air, which vibrates much as this little globe vibrates embedded in the jelly.

The result in a general way is this: The light coming from the blue sky is polarised in a plane through the sun, but the blue light of the sky is complicated by a great number of circumstances, and one of them is this, that the air is illuminated not only by the sun but by the earth. If we could get the earth covered by a black cloth, then we could study the polarised light of the sky with simplicity, which we cannot do now. There are, in Nature, reflections from seas and rocks and hills and waters in an indefinitely complicated manner.

Let observers observe the blue sky not only in winter when the earth is covered with snow, but in summer when it is covered with dark green foliage. This will help to unravel the complicated phenomena in question. But the azure blue of the sky is light produced by the reaction on the vibrating ether of little spherules of water, of perhaps a fifty-thousandth or a hundred-thousandth of a centimetre diameter, or perhaps little motes, or lumps, or crystals of common salt, or particles of dust, or germs of vegetable or animal species wafted about in the air. Now what is the luminiferous ether? It is matter prodigiously less dense than air—millions and millions and millions of times less dense than air. We can form some sort of idea of its limitations. We believe it is a real thing, with great rigidity in comparison with its density, and it may be made to vibrate 400 million million times per second and yet with such rigidity as not to produce the slightest resistance to any body going through it.

Going back to the illustration of the shoemaker's wax: if a cork will in the course of a year push its way up through a plate of that wax when placed under water, and if a lead bullet will penetrate downwards to the bottom, what is the law of the resistance? It clearly depends on time. The cork slowly in the course of a year works its way up through two inches of that substance; give it one or two thousand years to do it and the resistance will be enormously less; thus the motion of a cork or bullet, at the rate of one inch in 2000 years, may be compared with that of the earth, moving at the rate of six times ninety-three million miles a year, or nineteen miles per second, through the lumi-

niferous ether; but when we have a thing elastic like jelly and yielding like pitch, surely we have a large and solid ground for our faith in the speculative hypothesis of an elastic luminiferous ether, which constitutes the wave theory of light.

SCIENTIFIC SERIALS

Bulletin de la Société de Géographie, Paris, 3 Trimestre, 1884.—The principal portion of this number is occupied by papers of M. Huber, who spent the years 1878 to 1882 in Arabia on a scientific mission on behalf of the Department of Public Instruction. In the first he introduces 145 inscriptions which he found in various parts of Central Arabia on rocks. The second article is the first instalment (accompanied by a map) of an account of his numerous and extensive journeys in the same region, from Palmyra and Bagdad in the north, to Kheiber in the south. A glance at the route map shows that he has explored the greater part of this region during his prolonged stay there.—M. Petitin, in his account of his journey in Indo-China, gives a lengthy description of the difficulties and dangers which the traveller encounters in this peninsula. He was selected by Admiral de la Grandière when Governor of Saigon to make a geological investigation of Cochin-China, Siam, Hainan, and Formosa, but the death of the governor and the appointment of another whose views were different cut M. Petitin's explorations short. He saw enough, however, to give a brief account of the geology of Cochin-China, and to give the intending traveller much advice as to his arrangements and preparations. He also urges his countrymen to extend their dominion in the Indo-Chinese peninsula, especially in Tonquin, where the Red River affords them an opening into the heart of China.—M. la Meslle's paper on the eastern provinces of Australia is little more than a lively account of a journey in Queensland, while the object of M. Simonin's article on the ports of Great Britain—especially London, Liverpool, and Glasgow—is not quite apparent, unless it be to urge his countrymen to go and do likewise with their ports.

Verhandlungen der Gesellschaft für Erdkunde zu Berlin, Band xi., Nos. 6 and 7.—Herr Müller-Beeck, in the trade of Further India deals largely with trade routes into the Shan States and China. The Songkoi route into Yunnan he regards as one of great difficulty on account of the rapids. The delta also is constantly extending. Hanoi is now 110 miles from the sea; in the seventeenth century it was only half that distance. For half the year the upper part of the river is only navigable for boats of four tons, and when Manhao is reached, there is still a difficult land journey to Yunnan. The population also, he thinks, will form a grave obstacle to any regular trade by this channel.—Herr Buchta, in the Soudan and the Mahdi, deals purely with the political side of the Soudan question.—Prof. Seelstrang gives much interesting geographical and statistical information about the province of Santa Fé, in the Argentine Republic.—The usual notices of other societies and of new books conclude the number.

SOCIETIES AND ACADEMIES

London

Linnean Society, November 20.—Prof. P. Martin Duncan, F.R.S., Vice-President, in the chair.—Mr. A. Roope Hunt was elected a Fellow.—Mr. F. B. Forbes drew attention to specimens of pods and seeds used by the Chinese in place of soap. He stated that for ordinary detergent purposes an impure earthy soda and a lye made from ashes are employed. The leaves of *Hibiscus syriacus* and *Ginko biloba* are occasionally used for cleansing the head. The most favourite substance, however, is the fruit of certain Leguminosæ (Fei-tsao-tow). The late Daniel Hanbury figures these seeds as a species of *Dialium*. Dr. Porter Smith says they are the product of the *Acacia concinna* (*Mimosa saponaria*, Roxb.). Dr. Breitschneider asserts, on the contrary, that they belong to *Gymnocladus chinensis*, originally described by Baillon from pods only. Specimens at Kew lately figured in the "Icones Plantarum," are young leaves, fruit, and flowers from Foochow; those now exhibited (by Mr. Forbes) are, however, much finer examples from Ningpo and Wahu. The pods are roasted and kneaded into small balls used for washing clothes, and the head in bathing, but, on account of their unpleasant smell, they are prohibited in the public baths. The pods of *Gleditschia sinensis*, Lamk. (Tsao-chio) are used for the same purposes as *Gymnocladus*, those shown at the meeting being from Pekin and Shanghai district. One appears to answer to Dr. Hance's new *G. xylocarpa*. Bentham refers a South China tree to *G. sinensis*. Lamarck founded his species on a tree growing in the Jardin des Plantes, raised from seeds sent by Père Incarville 200 years ago from Pekin. It is doubtful if the northern and southern plants are identical. The pods are broken into small bits soaked in boiling water until an oily substance is floated, when they are ready for use. Another saponaceous substance is derived from *Sapindus makarosi* (the *S. chinensis* or *Kolreuteria paniculata*, Lam.), specimens of which were shown from Ningpo.—Messrs. H. and J. Groves exhibited specimens of (1) *Chara connivens*, collected at Slapton, South Devon, the only known British station, for no trace of the plant is now to be found at Stokes Bay; (2) *Chara canescens*, obtained from a pool between Helston and the Lizard, West Cornwall, by Messrs. Guardia and Groves, and also at Little Sea, Studland, Dorset, by Mr. Mansell Pleydell.—Mr. Geo. Murray showed dried and moistened examples of an Algæ, *Glœocapsa*, found by Mr. Pryer in birds'-nest caves in North Borneo.—Mr. J. G. Baker read the following letter from Mr. W. Brockhurst, of Didsbury, dated November 17, 1884:—"On April 2 I had the pleasure of exhibiting to the Society a number of prepared specimens of the daffodil, which appeared to prove that double daffodil flowers might produce seeds, and I advanced some arguments, based upon the observations I had made, to show that they were spread over wide areas in a wild state of seeding. The specimens showed the seed-vessels filled with ovules, but this did not fully prove that ripe seeds capable of germination would be matured. I therefore carefully observed a number of flowers of double daffodils (*Narcissus telamoneus-plenus*), and marked them as they went out of bloom, to prevent any mistakes. One of these produced a capsule containing nine shining black seeds, which were gathered on June 24, and at once sowed in a pot, and covered with a sheet of glass. Of these seeds four have already germinated, and show grass-like growths an inch above the soil. This therefore completes the proof."—Mr. W. T. Thiselton Dyer pointed out and made remarks on some sterile runners of *Mentha piperita*, and the remains of flowers of *Epilobium hirsutum*, both taken from a wreath found by Prof. Maspero in a tomb near Thebes, and supposed to be of the 20th or 26th dynasty; Mr. Dyer also exhibited fresh flowers of *Ipomea purpureo-cœrulea*.—Mr. Thos. Christy exhibited two specimens of *Lycaste Skinneri*, Lindl., one with two flowers on one stem, the other with an aborted lip adherent for the greater part of its length to the column. He also drew attention to samples of the tea (probably a species of *Ilex*) used largely in Bogota, but which is said to be deficient in flavour.—Mr. E. C. Stanford thereafter showed some of the products from seaweed, viz.:—Algin, the insoluble form of which (alginic acid) can be made into shirt-studs resembling horn, &c.; the soluble algin (or alginate of soda), which diminishes the brittleness of shellac, besides other uses.—A paper was read by Mr. E. M. Holmes on *Cinchona Ledgeriana* as a species. The author expressed the opinion that under the name of *C. Ledgeriana*, a number of varieties or forms, and probably some hybrids of *Cinchona Calisaya*, are now under cultivation in the British colonies. He believed that, if more attention were paid to the characters afforded by the bark of trees, taken in conjunction with the other botanical characters of flower and fruit, these varieties and hybrids would be more easily defined and recognised. He considers that the plant published under the name of *C. Ledgeriana* by Dr. Trimen was probably referable to Weddell's *Cinchona Calisaya*, var. *pallida*, as a horticultural form, for which the author proposed the name "*Trimeniana*."—A paper was read, notes on the habits of some Australian Hymenopterous Aculeata, by H. L. Roth. He states that the wasps of the genus *Pelopœus* (*P. lœtus*) build their nests on the walls, ceilings, legs of chairs, under the table, in cupboards, vases, between pictures and the walls, on curtains, in all sorts of crevices in the house, and on the roof. No place is safe from their intrusion. When a cell is completed, the wasp goes in search of spiders, and, seizing these, packs their half-dead bodies in the cell, lays an egg, and closes the cell-top; thereafter rows of cells are added to the primary one and dealt with in the same fashion, generally finishing with a streaked coating of mud, thus to deceive as to the real contents beneath. These wasps are infested with Dipterous parasites. Of the Australian ants, *Formica rufinigro* is numerous, bold, and destructive. They destroy the web of certain caterpillars and wriggle them out, when they fall a prey to a host of attendant

warrior ants.—Mr. E. T. Druery read a paper on a singular mode of reproduction in *Athyrium filix-fœmina*, var. *clarissima*. In a previous paper the author had shown that prothallia-bearing antheridia and archegonia were developed on the apex of pear-shaped bodies with the larger end downwards, in the place usually occupied by sori. In the present paper he brought forward evidence to show that these pear-shaped bodies were not developed from sporangia, but from a previous formation of thread-like bodies, a few of which became thickened, and developed into the pear-shaped bodies previously mentioned, the others remaining starved and undeveloped.

Zoological Society, November 18.—Prof. W. H. Flower, F.R.S., President, in the chair.—A communication was read from Mr. J. G. F. Riedel, C.M.Z.S., containing comments on certain passages in Mr. H. O. Forbes's paper on Timor-Laut birds, read before the Society on June 17.—A communication was read from Mr. H. Pryer, C.M.Z.S., giving an account of a recent visit to the edible-birds'-nest caves of British North Borneo In illustration of this paper, Mr. Pryer sent specimens of the swift (*Collocalia fuciphaga*), of its nest and eggs, of the *Alga* on which the bird was supposed to feed, and of the bat which inhabited the same caves.—Mr. Sclater read an account of some skins of mammals from Somali-land, which belonged apparently to five species. Amongst these was an apparently new form of wild ass, which was proposed to be called *Equus asinus somalicus*.—Mr. F. E. Beddard read a paper on the anatomy of the Umbrette (*Scopus umbretta*). The author observed that, as regards its exact systematic position, which had been hitherto a matter of doubt, he was inclined to place this peculiar form as a type of a separate family, between the herons (Ardeidæ) and the storks (Ciconiidæ).—A second paper by Mr. Beddard contained the results of some recent investigations into the structure of *Echidna*, and related to the presence of a persistent umbilical vein in that animal.—Captain Shelley read a paper on some new or little-known species of East African birds. Three of these were described under the names *Muscicapa johnstoni*, *Pratincola axillaris*, and *Nectarinia kilimensis*. The collection, which contained altogether ninety-four specimens, referable to thirty-eight species, was the first-fruits of Mr. H. H. Johnston's expedition to Kilimanjaro.—A communication was read from Mr. J. H. Gurney, F.Z.S., on the geographical distribution of *Huhua nipalensis*, with remarks on this and other allied species of owls.

Chemical Society, November 20.—Dr. Perkin, F.R.S., in the chair.—The following gentlemen were elected Fellows:—F. Broughton, F. J. Down, L. Ehrmann, F. G. Holmes, J. Hulme, C. Thompson, W. F. Wigley.—The following papers were read:—On some new paraffins, by Khan B. B. Sobrabji. The author has prepared cetane boiling at 278°, dicetyl melting at 70°, ethylcetyl and diheptyl.—On additive and condensation compounds of diketones with ketones, by F. R. Japp and N. H. J. Miller. The authors have studied the action of potash of various strengths on mixtures of phenanthraquinone and acetone. Additive compounds were obtained containing one molecule of the first substance to two of acetone, and another containing two molecules of phenanthraquinone to one of acetone. Condensation compounds were formed from the above additive compounds by the abstraction of the elements of water. The authors have also studied the action of potash upon mixtures of benzil with acetone and with acetophenone respectively, and have obtained acetobenzil and acetophenonebenzil.—On the vapour-pressure of acetic acid, and on a new method of determining the vapour-pressures of liquids, by W. Ramsay and Sydney Young. The authors have used a species of still into which a thermometer dips, the bulb of which is covered with cotton-wool moistened with the liquid. On heating, the liquid evaporates from the cotton-wool without ebullition. Results obtained agree with those obtained in the ordinary way. Perfectly concordant and regular results have been obtained with acetic acid.—On the action of the halogens on the salts of trimethylsulphine, by L. Dobbin and Orme Masson. The authors conclude that all the haloid salts of trimethylsulphine combine directly with chlorine, bromine, iodine, and iodine monochloride. In no case is one halogen replaced by the other. The authors have partly investigated the action of the halogens on trimethylsulphine sulphate.—Note on the heats of dissolution of the sulphates of potassium and lithium, by S. U. Pickering. The salts do not seem to form isomeric modifications such as exist in the case of sodium sulphate.—On the application of iron sulphate in agriculture and its value as a plant food, by A. B. Griffiths. The author finds that half a hundredweight of sulphate of iron per acre increased the yield of beans from 28 bushels to 44 bushels, of turnips from 13 tons to 16½ tons, but little effect was produced on cereals.—Notes on the chemical alterations in green fodder during its conversion into ensilage, by C. Richardson. The author confirms the results obtained by Kinch and Kellner, that a considerable increase in the non-albuminoid nitrogen takes place in the conversion: no such change occurs during the ordinary drying of fodder. The author used maize in his experiments.—On the decomposition of silver fulminate by hydrochloric acid, by E. Divers and Michitada Kawakita. The authors have studied the action of dilute and strong hydrochloric acid on this salt. With dilute acid the principal products are hydroxyammonium chloride and formic acid; if the acid is strong, much ammonium chloride is produced. A small quantity of hydrocyanic acid is always formed. They could not obtain any oxalic acid by decomposing mercury fulminate with hydrogen sulphide in ether. They have also studied the action of hydrochloric acid on fulminurates.

Paris

Academy of Sciences, November 24.—M. Rolland, President, in the chair.—Experiments with the chlorhydrate of cocaine (continued), by M. Vulpian. Further experiments made on snails (*Helix pomatia*) and fresh-water prawns (*Astacus fluviatilis*, F.) show that this anæsthetic is less efficacious in the case of invertebrate than vertebrate animals.—Note on the algebraic relations between hyperelliptic functions of the *n* order, by M. Brioschi.—On some reactions of the sulphuret of carbon, and on the solubility of this substance in water, by MM. G. Chancel and F. Parmentier.—Remarks by M. Daubrée on M. Nordenskjöld's "Voyage Round Europe and Asia," in connection with the French translation of that work presented to the Academy.—Note on the action of heat on electric piles, and on the law of Kopp and Wœstyne, by M. G. Lippmann.—Statistical note on cholera in the Paris hospitals since the outbreak of the epidemic on November 4 till the present time, by M. Emile Rivière. During this period 971 patients (579 men, 392 women) were treated in the various hospitals. Of these, 511 succumbed (302 men, 209 women), and 239 (129 men, 110 women) have so far been completely cured. The mortality has thus been 52·33 and 53·31 for men and women respectively. The working classes—rag-gatherers, seamstresses, washerwomen, masons, bricklayers, and shoemakers—have supplied the largest relative number of victims. These have almost invariably been persons of feeble constitution, subject to chronic disorders, exhausted by previous excesses, exposed to extreme physical destitution, or dwelling in the lowest slums of the French capital and its suburbs.—Remarks on the second instalment of the new map of Tunis prepared in the War Office on a scale of 1 : 200,000, by Col. Perrier. This instalment comprises six sheets, embracing the districts of Kef, Kairwan, Mahedia, Feriana, El Jem, and Sfax, based on surveys executed on the spot.—Presentation of the "Annals of the Ouro-Preto School of Mines," by the Emperor Dom Pedro II., with remarks by M. Daubrée.—On the condensation of the solar nebula on the hypothesis of Laplace, by M. Maurice Fouché.—Remarks on the nature of the curve known as Poinsot's erpolodie, by M. de Sparre.—On the involution of superior dimensions, by MM. J. S. and M. N. Vanecek.—Dynamo-electric machines: experimental confirmations of the two reactions, on the effective values of the inner resistance and of the inductor magnetism, by M. G. Cabanellas.—Action of water on the double salts, by M. F. M. Raoult.—On the composition of the gaseous products resulting from the combustion of pyrite, by M. Scheurer-Kestner.—New experiments on the rotation of crops in connection with the cultivation of beetroot, by M. P. P. Dehérain.—On the appearance and spread in France of the parasite of the beetroot known as *Heteredora Schachtii*, by M. Aimé Girard. To this parasite, the author thinks, is largely due the partial failure of this year's crop, which showed a deficit of 20 per cent. in the weight of the roots, besides a decrease in the yield of saccharine, which in some of the northern districts amounted to 12 or 14 per cent.—On the formation of vegetable acids in combination with potassa and lime bases, on the nitric substances and the nitrate of potassa developed in the saccharine plants, beetroot and maize, by M. H. Leplay.—On the characteristic smell and toxic effects of the products of fermentation produced by the comma-bacillus of cholera, by MM. W. Nicati and M. Rietsch.—On

cholera and cholemia, by M. W. Nicati. From the experiments recently made in the chemical laboratory of the Faculty of Sciences at Marseilles it seems established that biliary acids are relatively more abundant in the blood of the victims of cholera than in others. But the author is unable yet to decide whether in their case death is to be attributed to cholemia.—Note on infectious and parasitic pneumonic affections, by M. Germain Sée.—Experiments on the efficacy of disinfecting agents in the case of chicken cholera, by M. Colin.—On the virulence of the bubo accompanying soft chancre, by M. I. Straus.—On the luminous intensity of the spectral colours; influence of the state of the retina in determining light effects, by M. H. Parinaud.—On the appendices to the jaw of grinding insects, by M. Joannes Chatin.—On the floral polymorphism and the fertilisation of *Lychnis dioica*, L., by M. L. Crié.—Remarks on Dr. Ladislas Szajnocha's memoir on the Cephalopods of the Elobi Islands, West Coast of Africa, by M. Daubrée.

BERLIN

Meteorological Society, November 4.—Dr. Hellmann, following up an account of the most recent works in the department of meteorological literature, which he concluded with a full discussion of Mr. Blanford's rain-map of India, communicated his own observations regarding the rain conditions prevailing in Heligoland. The measurements there obtained had given an annual rainfall of 72·50 inches, an amount far surpassing that which had been observed at any of the neighbouring stations on the west coast of Schleswig and at the mouth of the Elbe. The speaker, having last summer made a tour of inspection, and convinced himself, from the instruments in use and their situation, of the accuracy of the registrations above referred to, explained the excessive rainfall in Heligoland by the circumstance that the steep coast, shooting up almost perpendicularly to about 164 feet above the level of the sea, forced the moist sea winds suddenly aloft, and so caused them to cool and condense both very rapidly and to a great extent. For the sake of testing the correctness of this explanation he had got another rain-gauge set up on the dunes at about 16 feet above sea-level, the registrations of which would next year be compared with those at the higher level. A second point in which the rain conditions of Heligoland deviated from those observed at the neighbouring stations on the coast respected the annual course of the rainfall. It was found that in North-West Germany the rainfall indicated a minimum in the middle of April and a maximum in August. In Heligoland, on the other hand, though indeed the minimum of rainfall occurred likewise in the middle of April, the maximum was attained in November. Dr. Hellmann sought an explanation of the postponement of the rain maximum in this latter case in the circumstance that in the yearly course of the temperature of the water and the atmosphere the difference between the two was greatest in November, the water at that time showing a temperature as much as 3°·6 F. warmer than that of the air.—Prof. Spörer gave a brief sketch of the present period of sun-spots. The spot periods being counted from minimum to minimum, the commencement of the present spot period was to be referred to 1878·8. So far as had been hitherto observed the present was distinguished from the two last spot periods by two peculiarities; first, that the maximum in the present period appeared to have occurred 0·4 of a year later than in the previous periods, and, second, that during the maximum the distribution of the solar eruptions showed an essentially different character from that usually obtaining. In the former periods it was observed during the maximum that the greatest concourse of spots surrounded with faculæ occurred in the median latitudes of the sun, that they were completely wanting towards the poles, became less numerous also towards the equator, and only at the equator itself did they again become somewhat more crowded. In the rotation of the sun those eruptions showed a heliographic displacement towards the equator, in contrast to the spots free from faculæ which, in the course of rotation, wandered towards the poles. During the minima of the spot periods the maximum of the eruptions was generally found in the neighbourhood of the equator. In the present period, again, the greatest concourse of eruptions surrounded with faculæ was found towards the equator during the maximum as well, a phenomenon usually occurring at the time of the minimum. The present, on the other hand, resembled former periods in the circumstance that it was only on rare occasions that the concourse of spots was alike on both hemispheres of the sun. In the majority of cases either the northern hemisphere presented a more copious display of spots than the southern, or the southern mustered them in larger numbers than the northern.

STOCKHOLM

Academy of Sciences, November 12.—Prof. Gyldén communicated the results of the Meridian Conference in Washington, according to the report of the Swedish delegate Count Lewenhaupt, and gave an account of his own paper "On the origin of comets."—Prof. Lindström exhibited a fossil scorpion recently found near Wisby in the Silurian formation of Gotland, and remarkable as the most ancient air-breathing land-animal at present discovered.—Prof. Retzius presented the last volume of his great work "Das Gehörorgan der Wirbelthiere," and made some remarks on its contents.—Prof. Nordenskjöld communicated a "Catalogue of the Meteorites in the Swedish Museum of Natural History," by Herr G. Lindström, Assistant Mineral Department.—Prof. Wittrock gave an account (1) of a paper by Dr. Johansson, of Upsala, "On Fungi from Iceland," and (2) of another paper by Dr. Alb. Nilsson "On the mechanical function of the sheaths of *Dianthus banaticus*, Heuff."—The Secretary presented the following papers:—On a quantity of the electrical potential, by Prof. Dahlander.—Sur la sommation des puissances semblables des *n* premiers nombres entiers, by Dr. C. O. Boije, of Gennäs.—On some recently-published mathematical papers from the seventeenth century by Bierens de Haan, by Dr. G. Eneström.—On a proposition from the theory of the elliptic functions, by E. Phragmén.—On substituted cyanamides and melanins, by Dr. P. Claësson.—On *Mergus anatarius*, Eimbeck, found in Sweden, by G. Kolthoff.—On a new Isopod from the coast of Sweden, by Dr. C. Bowallius.—On minerals occurring at Vestra Silfberg, by Dr. Mats Weibull.—A catalogue of the phænogamous plants and ferns of Jemtland, by Dr. P. Olsson.

VIENNA

Imperial Academy of Sciences, October 23.—Report on his journeys in the Balkan Peninsula, by F. Toula.—The geological exploration of the Central Balkans and adjacent regions, by the same.

CONTENTS

THURSDAY, DECEMBER 11, 1884

HEALTH LABORATORIES AS THE RESULT OF THE HEALTH EXHIBITION

MEN of science have thus far regarded the South Kensington Exhibitions of the last two years with very languid interest, if not with some suspicion. There has been throughout some show of scientific intent and much promise of serious result. Needless to say, however, that in regard to the Fisheries Exhibition, whatever may be in store for the future, very little of what was promised of solid or scientific result has thus far been definitely realised. That Exhibition achieved a certain success in technical interest and much was hoped in financial result, but there has been a remarkable reticence in respect to the surplus obtained and its proposed disposal. Little, if anything, has been announced in reply to the urgent requests that have been put forward for information on this subject as to the promotion of new knowledge which should aid the protection of the harvest of the sea, or help to give us information, of which we stand sadly in need, as to the best means of favouring the growth and hindering the destruction of the marine staple of food. So far the Marine Biological Association, which has been started by voluntary effort, has not received any promise of or share in the large sum of money which must now be standing to the credit of the Fisheries' Council. That body are in the happy position of having a continuing receipt as lessors of the buildings just vacated by the International Health Exhibition; they will receive a handsome sum for the next two years at least, and probably also in the succeeding years, from the Exhibitions already planned and in course of arrangement. They have a future before them rich in golden promise, and it is much to be hoped that they will not be unmindful of the new Marine Association. The Council of the International Health Exhibition have been more prompt in declaring the results of their work and in announcing some of its probable issues. Of this Exhibition also it was said, while its doors were open, that the element of display and of public attraction appeared to be much more prominent than did the scientific and solid objects which the great body of busy chemists, sanitarians, and engineers were summoned to assist by their work on the General Committees and on the juries. It will be found, however, by the statement which Mr. Ernest Hart makes in another column of the work done and the results achieved, that, although the serious side of the Exhibition was much less a subject of comment than its more entertaining features, the Council have steadily held the former in view and are likely still to do so in the proposed disposal of the surplus in promoting solid objects of national importance. In this Exhibition for the first time the Council went outside the ordinary routine of exhibits obtained from commercial or speculative sources, and at their own cost brought together and created departments of which the object was purely educational. Thus on the sanitary and unsanitary houses there appears to have been expended nearly 1000*l*., and probably much more than that on the literature of the Exhibition, including a considerable series of hand-books by skilled persons, devoted to the popular exposition of public and private hygiene, and the reports of conferences and lectures. A library was brought together of sanitary and educational works—about five thousand in number. Although far from complete, it was in many departments, especially in those relating to civic, official, and foreign sanitation, more extensive than any that had yet been collected. Of this an excellent printed catalogue was prepared, which is of itself a useful book of reference. Besides this, and perhaps far more important, was the creation of two health laboratories, under the direction of Profs. Corfield and Cheyne. By special application to the French Government a full exhibit was also obtained, illustrating the nature of the work and showing the instruments employed by M. Pasteur and M. Mique in their respective institutes. It is well known that laboratories of this kind are especially important for the scientific study of the bacteriological problems which have to be worked out, and which form the basis of the most important public health researches of the present day. The scheme which was presented to the Council in the early days of its work for the formation of these laboratories contemplated the creation of temporary laboratories, which should be put in working order and should demonstrate the nature of the work carried on in such laboratories, and its close and immediate connection with the interests of the health of man, and with investigations of high commercial value to every department of agriculture, and with the study of the costly epizootics which affect the prosperity of the grazing interest and influence of the food-supply of the nation. These laboratories have been in every sense successful. We have already noticed with satisfaction the paragraph in the report which the Council presented on the closing day of the Exhibition, in which they referred to a proposition that had been laid before them for establishing these health laboratories on a permanent footing as the best possible application of the surplus. The amount of that surplus has not yet been determined, and it is premature to speculate upon it. There is reason to fear that it will be much less than has been publicly rumoured. We have seen it anticipated in print that it will amount to nearly 30,000*l*. On the other hand, we have it on good authority that it is not likely to exceed half that sum. However this may be, it is satisfactory that the address, of which we print a part, and which has a semi-official value, coming from a member of the Executive Council, with the Chairman of the Council presiding, adverts to this application of the surplus almost as though it were a settled matter. Mr. Ernest Hart may of course speak with some excessive hope, inasmuch as it is known that the first establishment of these laboratories was due to his efforts, and they were formed upon the scheme which he drew up for the purpose. The proposition for making them permanent proceeds comes also from him, and no doubt he has a paternal hopefulness which may be excessive. There is, however, evident reason for accepting this most desirable application of the funds as the most probable issue, seeing that the Duke of Buckingham so heartily indorsed it in his speech at the Society of Arts at the close of the address, and that Sir Frederick Abel, also a member of the Exhibition Council, and not likely to speak with other than official caution, stated that Mr. Hart's scheme had now obtained,

he believed, a pretty unanimous consensus of opinion in the Council. Outside, opinion has at once declared itself with strong approval of this application of the funds, and it is indeed evident that, if the Council can succeed in establishing health laboratories which shall find for the health students of this country establishments properly equipped such as those of Pasteur, Koch, and Miquel, the Exhibition will not have lived its short life in vain, but will leave behind it an institution not only of permanent value but of growing importance and of large promise. The Commissioners of 1851 will certainly see with great satisfaction this liberal intention of the Executive Council of the Health Exhibition to add to those laboratories which they have already provided one which is so greatly needed to complete the means of study and of education which South Kensington supplies in other departments of technical and biological research and teaching. They will probably make no difficulty—or, rather, they will have the strongest reason which a desire for national usefulness will give them to overcome any difficulty—in providing a suitable site for such laboratories. Even if the means which the surplus may provide should not be adequate for the establishment and endowment of such a laboratory, there is little doubt that, with this good beginning, so much may be effected as will afford the best possible reason and the largest inducement to societies such as the Royal Society, the British Medical Association, the British Association, and others to make grants to students conducting research in the laboratories. The Government can hardly refuse to make grants in aid of an institution which in any other country than this would be wholly supported by State funds—witness the health laboratories of France and Germany, which are liberally maintained by State endowments. In this country, however, we are accustomed to look to private enterprise, and the liberality of societies or committees, to furnish at least a large part of the funds required for scientific research or endowment, and it is satisfactory to know that the Council of the International Health Exhibition have favourably considered the proposition that they should take the first step in this useful direction. Every one interested in the promotion of real health-progress will trust that it will soon be an accomplished fact.

THE BUTTERFLIES OF EUROPE

The Butterflies of Europe. Described and Figured by Henry C. Lang, M.D., F.L.S., &c. Pp. 396, Super-Royal 8vo, with 77 Chromo-lithographic Plates. 1881–1884 in parts. (London: L. Reeve and Co., 1884.)

FOR some years past the writer of this notice has, almost annually, formed one of the members of that large class of Englishmen who, each year, spend a few weeks in the Alpine and sub-Alpine districts of Europe for "relaxation." The writer prefers to leave it to the taste and fancy of the individuals interested to define the meaning of the latter term. He has naturally met hosts of "foreigners" of different nationalities engaged in the same pursuit. Whatever may be the state of the weather or other conditions incidental to travelling of this kind, those *voyageurs* of Gallic origin succeed in amusing themselves after their own special fashion. The Teutonic element also succeeds, but in an entirely different manner. The Americans seem tolerably successful. They leave home to "do" Europe, and they "do" it, in their own businesslike fashion,—business and pleasure are carried out on the same principles. Then there comes the large class of our own countrymen and countrywomen. We must confess that, according to our observation, the majority of these do not bear the outward appearance of enjoyment (especially the male portion). There is something apparently wanting. They have left their business or profession behind them, and the void thus occasioned cannot be satisfactorily filled in. From these must, of course, be separated those who find enjoyment in the excitement of Alpine climbing, and some others. Amongst these others are those who may be seen with *vasculum* at back, or insect-net in hand (very frequently in ill-disguised clerical garb), enjoying *themselves* to an extent unknown to, and often not understandable by, their fellow-countrymen who have voluntarily placed themselves under the same conditions. Probably a still larger amount of Teutons may be observed provided in the same way. And only this year we found ourselves seated next to a New England divine and his wife, and overheard the latter read out to her husband an advertisement of a butterfly-book, with the remark, "That would just suit *you*."

In the foregoing notes we have tried to draw a picture which we (perhaps we are prejudiced) believe to be tolerably natural. The pursuit of some branch of natural history studies on our travels adds a zest to the other conditions of surpassing value. If pursued systematically, it can hardly be termed "relaxation," if taken to mean "doing nothing." But if the work be harder (and it often is very much harder) than ordinary occupations, it is often the one thing needed, both for health and enjoyment.

Of the bearers of the insect-net in the Alps the majority occupy themselves with butterflies and moths, and the majority of these again with butterflies only. To an Englishman accustomed only to his own meagre, and declining, butterfly fauna, the wealth and beauty of forms is marvellous. With the exception of a small, but useful, manual, published by Mr. W. F. Kirby more than twenty years ago, and which consists almost entirely of laconic descriptions without figures, there has been, up till now, no work in the English language that enables collectors of European (as opposed to British) butterflies to name their captures without the troublesome comparison of some noted collection. These therefore will thank Dr. Lang for having supplied the deficiency, and in a generally satisfactory manner. The author has adopted no new system of his own. He follows Staudinger's German Catalogue, describing (for the most part originally) and figuring those species that occur in Europe proper, and simply describing those that have not occurred in "Europe," but still form part of the "European Fauna" (a term becoming daily more difficult to define). We think there is evidence of a little too much dry routine in the text: the descriptions appear to be excellent, and there is always a notice of the larvæ when known, and tolerably copious geographical information as to distribution, but the class of readers who will mainly use the book would be more readily caught by a mixture of

popular matter, recalling to their minds some of the scenes in connection with their own captures, or serving as a stimulant for future expeditions. But after all it is the *plates* that will be most frequently consulted. Of these there are seventy-seven, mostly crowded with figures, and including a few of transformations. Without the recent adaptation of chromo-lithography, in a superior form, to natural history subjects, the publication of such a work as this (at the price) would have been impossible. The author estimates that there are more than 800 figures on these plates. It is impossible here to criticise them *seriatim*. Those subjects that appear the most difficult are often the best (perhaps more detail in the way of "stones" was used on them), and we are much pleased with the *Hesperidæ*, which, easy as they may look at first sight, must prove very troublesome of application. The "Blues" and "Coppers" (*Lycænidæ*) are fair, but naturally fail in effect where metallic colours are necessary. The worst, to our mind, are those of the *Satyridæ* (of which our "meadow-brown" is a familiar example), and yet they *look* the easiest: we think here there is evidence of trying to make too many species, with varying shades of practically the same colour, accommodate themselves to one "stone." The size is rather too large for a book to be used as a travelling companion, but we think it is rather intended for home study. Paper and type are very good (the former almost unnecessarily so). There is not much to find fault with in the way of uncorrected errors. This is satisfactory, because careless correction is the crying evil of the present day, even in works claiming a much higher scientific position than does this, and often shows up the amount of knowledge possessed by writers of the authors and works they quote. But such glaring errors as the following should not have escaped correction:—Page 47, "Illus. Mag." for "Illiger's Mag."; p. 61 (and elsewhere), "Wein" for "Wien"; p. 153, "Sellmann's" for "Silliman's"; p. 380, "Thurnberg" for "Thunberg"; and, as a crowning morsel, p. 379, "Aumer Kungen" for "Anmerkungen." In notices of some of the recent additions from Central Asia, the author uses indiscriminately (sometimes on the same page) "Samarcand" and "Maracand" as localities; we thought it was generally understood that the latter is only the ancient name of the former.

We have hitherto dealt with this work from a popular point of view. But there is also the scientific side of the question. The book will be of service as collectively giving good descriptions and figures of all known European species brought down to date, and thus avert the necessity of search through a multitude of scattered publications; and in this it will be useful to other than English readers.

On the title-page the author adopts a super-title—"Rhopalocera Europæ." This we think a pity in a work otherwise entirely in the English language.

R. McLACHLAN

ELEMENTARY MATHEMATICS

Lehrbuch der Elementaren Mathematik. V. Schlegel. Pp. 712. (Wolfenbüttel, 1878-1880.)

WE have not had the good fortune to meet with this work, but having now before us an elaborate notice of it by M. Hoüel in the *Bulletin des Sciences Mathématiques et Astronomiques*, December, 1882 (pp. 301-313), we have thought that a few passages from the notice would be acceptable to some of our readers, and lead them to a personal examination of the original treatise.

The writer's opening remarks have much truth in them:—"Nous sommes habitués depuis longtemps à considérer l'apparition d'un traité élémentaire de mathématiques comme un événement pédagogique ou commercial n'ayant rien de commun avec la science pure. Si l'on met à part quelques honorables exceptions, c'est toujours le même livre qui reparaît sous une couverture de couleur différente, avec quelques pages transposées, quelques propositions secondaires introduites ou supprimées, quelques démonstrations modifiées sinon perfectionnées, quelques développements de plus suivant les tendances des programmes officiels. Quant à la manière d'exposer les principes fondamentaux de la science, rien n'est changé. Les découvertes qu'on a faites dans les hautes mathématiques depuis un siècle et qui ont si admirablement éclairci les difficultés que présentaient encore les éléments d'algèbre semblent étrangères à nos auteurs, qui expliquent les imaginaires comme au temps de Bézout et de Lacroix, et présentent parfois à leurs lecteurs des notions géométriques en arrière de beaucoup sur celles qu'exposait Euclide il y a plus de deux mille ans. . . . En Angleterre, l'enseignement est resté ce qu'il était au temps de Barrow et de Simpson; heureusement le vieil Euclide a été choisi et fidèlement conservé à l'abri des prétendus perfectionnements des traités modernes."

M. Victor Schlegel is a pupil of H. Grassmann, and his present work is inspired by the bold views of the author of the "Ausdehnungslehre." It consists of four volumes devoted to arithmetic, algebra, plane and solid geometry, and plane and spherical trigonometry. Vol. i., "Arithmetik und Combinatorik" (182 pp.), treats of elementary algebra and of the theory of combinations. "Le tout est exposé avec une concision qui n'exclut pas la clarté, et avec une rigueur irréprochable." The reviewer's attention is especially directed to an analysis of vol. ii., "la partie vraiment originale de l'ouvrage." In 222 pages are laid down the principles of plane geometry, the ideas in which are those first introduced, we believe, by Grassmann. A full statement is given of the fundamental hypotheses, and the treatise consists of two sections. The first, "Geometry of Figures in Motion," naturally discusses the geometry of the straight line and of the plane; the second, "Geometry of Figures at Rest." A collection of 737 exercises closes the book. The following remark by M. Hoüel is deserving of a place here:—"La tendance de la nouvelle école à remplacer le raisonnement par le coup d'œil nous semble éminemment dangeureuse. Le sentiment de la forme est un précieux auxiliaire, auquel les illustres inventeurs de la géométrie pure ont dû une grande partie de leurs découvertes: mais rien en mathématiques ne peut dispenser de la démonstration, d'autant plus que cette partie de la tâche est en général la plus aisée. Dans le cas actuel, la marche d'Euclide n'est pas plus longue, et ne laisse aucun doute dans l'esprit."

The third volume, Rectilineal (or Plane) Trigonometry, is founded, in like manner with the second, on a treatise on the subject published by Grassmann in 1865.

Approving in the main of this volume, we gather that the reviewer differs from the author on some points. M. Hoüel's views we have lately come across in "Rémarques sur l'enseignement de la Trigonométrie" (a paper originally printed in the *Giornale di Matematiche*, t. xiii., 1875, and reproduced in the *Mémoires de la Société des Sciences Physiques et Naturelles de Bordeaux*, 2e série, tome v., 1882, pp. 197-209). He altogether approves of M. Schlegel's appendix, containing a table of *rational* right- and oblique-angled triangles "où l'on puiser d'excellents exercices de calcul numériques."

The fourth volume, devoted to Solid Geometry, is prefaced by an introduction in which the author discusses the most convenient methods for getting clear ideas of figures in space, viz., by the use of models in relief and by stereoscopic images (at the end are plates, corresponding, we presume, to Clerk Maxwell's stereograms, of polyhedra).

"Un auteur se disposant à écrire un traité classique ne saurait trouver une meilleure préparation que la lecture du livre de M. Schlegel, où il apercevrait tant d'horizons nouveaux, inconnus à la routine, et qui eux-mêmes peuvent conduire à des découvertes ultérieuses."

We must not omit to state that M. Hoüel objects to some of the ideas put forward; but the grounds on which he commends the "Lehrbuch" (in addition to others adduced above) are thus summed up:—"Quoi qu'il en soit, nous sommes si peu accoutumés à rencontrer dans les manuels de géométrie des idées neuves et hardies, que nous n'hésitons pas à saluer comme un heureux événement dans la littérature géométrique l'apparition de ce traité, où le disciple fidèle de Grassmann s'est fait le sagace interprète des idées du maître sur l'enseignement élémentaire."

OUR BOOK SHELF

The Edible Mollusca of Great Britain and Ireland. With Recipes for Cooking Them. By M. S. Lovell. (London: L. Reeve and Co., 1884.)

We have received the second edition of this interesting, useful, and in some respects most amusing book. The primary object of the author is to call attention to the qualities and merits of many kinds of shell-fish which are as nutritious as others which are generally known, but which are rarely met with in our markets, or are only used locally for food, while the proper modes of cooking them are scarcely known. Accordingly all the known species of edible shell-fish on our coasts are here described in succession, with the various modes of cooking them. This alone would make the volume of great use at a time when we are going to the uttermost ends of the earth for the sources of our food-supply, and when public attention has been so powerfully drawn to our fisheries by the Exhibition of last year at Kensington. But when we add that the writer has collected from the most varying sources—from an "old M.S." to the Bridgewater Treatises, and from Athenæus to the latest book of travels that is having its little day,—a mass of curious lore about shell-fish, their uses, and the mode of catching them in various parts of the globe, their medicinal properties, the popular superstitions about them, &c., it will be perceived that this is much more than a work on natural history *plus* a cookery-book. If the title were not too suggestive of dulness for such an amusing volume, one would feel inclined to say that "Encyclopædia of the Edible Mollusks" would be a suitable title. And when we examine the formidable list of works "referred to or consulted" at the end, filling with mere titles thirteen pages, we cease to wonder at the out-of-the-way information contained in the volume. Of the nineteen sections in which the subject is treated, that on the *Ostreadæ* is, as might be expected, the longest, although that on the *Helicidæ*, which is also comparatively long, appears to us the most amusing. We hear of many infallible corn solvents, corn-destroyers, and the like, but the prescription of Master Ralph Blower, who wrote a certain "Rich Storehouse or Treasurie for the Diseased," possesses at least the merit of originality. Here it is. "Take black sope and snailes, of each a like quantitie, stampe them togither, and make plaister thereof, and spread it upon a piece of fine linnen cloth, or else upon a piece of white leather, and lay it upon the corne, and it will take it cleane away within seven dayes space." Master Blower who, by the way, wrote "for the benefit of the poorer sorts of people that are not of abilitie to goe to the Physicians," supplies the recipes for other cunning decoctions of snails, as do several other physicians who are quoted. Snail-water appears to have been considered a sovereign cure for consumption; but it may not be generally known that a large trade in snails is carried on for Covent Garden Market in the Lincolnshire Fens. They are sold at 6*d.* per quart, and it appears that they are still much used for consumptive patients and weakly children. Of all the many uses of snails in various parts of the globe, the strangest perhaps is that discovered by the London adulterator. They are much employed, the author assures us, in the manufacture of cream, being bruised in milk and boiled, and a *retired* milkman pronounced it the most successful imitation known! There are, we should say in conclusion, many beautifully coloured illustrations.

Forestry in the Mining Districts of the Ural Mountains in Eastern Russia. Compiled by John Croumbie Brown, LL.D., &c. (Edinburgh: Oliver and Boyd; London: Simpkin, Marshall, and Co., 1884.)

Still another book on forestry by Dr. Brown, uniform in size and binding with those that have preceded it. We have before alluded to the readable character of Dr. Brown's books, and the one before us is no exception to those on "The Forests of England" and the "French Forest Ordinance of 1669"; indeed it is perhaps more popular in its style, which Dr. Brown is not entirely responsible for, as he states on his title-page that it is a compilation, and the free use of inverted commas shows it to be so to a great extent. Though the book may contain a very good description of the country under consideration and accounts of the several journeys made in Russia, we are bound to say that not more than half deals with forestry matters. Thus we have one chapter devoted to the journey from St. Petersburg to Moscow, including a description of the Nijni Novgorod Fair. Another chapter describes the "Mishaps and Difficulties Experienced in Travelling"; another "Metallurgy"; and another "Depressed Condition of Mining, Smelting, and Manufacturing Establishments." The chapters that deal with forestry in some form or another are on "Forest Exploitation in the Government of Ufa"; "Abuses in Connection with the Exploitation of Forests"; a short one on "Forests," &c.

It may be stated that Dr. Brown's several works on "Forestal Literature" were awarded a silver medal at the recent Forestry Exhibition in Edinburgh, a fact to which he draws attention at the commencement of the present volume.

Die pyrenäische Halbinsel. Von Dr. Moritz Willkomm. II. Abteilung: "Spanien." (Leipzig: G. Freytag, 1884.)

This forms one of a series of volumes on the countries of the world, and appears to be part of a German "Universal-Bibliothek" entitled "Das Wissen der

Gegenwart." It is clearly printed, has numerous illustrations, and the information, which is excellently arranged, is brought down to the latest date and is very full. The volume and the series are of a kind more numerous and popular in Germany than in England.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Prime Meridian Conference

In *La Nature* of November 22 (p. 399) appears what is represented as information obtained at the meeting of the Academy of Sciences at Paris on November 17. It is stated that the proposal made by Prof. Janssen at the Meridian Congress at Washington, relative to the application of the decimal system to the measurement of angles and time, obtained a majority of 24 votes against 21, notwithstanding the "opposition *très-vive*" of the English and Americans. The vote to which reference is made was not on the merits of Prof. Janssen's proposal, but merely whether the opinion of the President that the Congress was not competent to entertain it, should be upheld or not. The decision being in favour of considering it, the proposal was accepted unanimously. On turning to the *Comptes Rendus* of the Academy I find it simply stated that M. Janssen observed that his proposition had been accepted almost unanimously, and without a vote in opposition.

La Nature further refers to the British delegates as having made the discussion on the prime meridian a question of "*amour-propre*," and as having converted to the British cause most of the representatives present. This statement is no less inaccurate and misleading than the former. As M. Janssen himself remarked at Washington, England did not make the proposal to adopt the meridian of Greenwich, and though the British delegates differed from their French colleagues as to the considerations which should govern the choice of a prime meridian for longitude, there was not a word said by them to justify what is stated by *La Nature*, and it is manifestly absurd to speak of the conversion of the representatives to the British cause, inasmuch as it is a perfectly well-known fact that almost every one of them came to Washington with instructions from their own Governments to vote for the Greenwich meridian. In justice to M. Janssen I wish to add that the *Comptes Rendus* makes no reference whatever to anything having been said by him on this subject.

It is greatly to be regretted that a journal professing to be scientific should have given a colour to the discussions which took place at Washington that forcibly suggests a deliberate intention of exciting national jealousies and animosities.

RICHARD STRACHEY,
Late Delegate at Washington

December 5

It is to be regretted that the French delegates have declined to accept some of the resolutions of the Prime Meridian Conference, but it is to be hoped that their non-adherence is only temporary; at the same time it must be admitted that their contention that Greenwich is not a scientific starting-point for a universal meridian has much to be said for it; the zero of longitude ought certainly to be defined somewhere on the equator, and if it were to be hereafter so defined at a point on the equator having the same meridian as the Greenwich instrument it is probable that all difficulty would be removed. The French are known to attach importance to ideas, and doubtless do not like the apparent supremacy which would be conferred on Greenwich if it were made the actual centre of departure. The point in question lies somewhere in the Atlantic Ocean, and is therefore on perfectly neutral territory.

One of the great obstacles to the introduction of the French metrical system into this country lies in the forbidding and inconvenient nomenclature attached to it. If the long compound names were translated into short English monosyllables, such as *met*, *kim*, *mim*, &c., not only would their use be greatly advanced and facilitated, but the French nation would in time borrow back from us our nomenclature. Such words offend at first sight by their new and startling aspect, but this all wears off in an hour or two; they require however to be started by some one in authority. There is a strange and unreasonable prejudice in the present day against the introduction of new monosyllabic words without derivation, which happily for us did not prevail in the days of our early forefathers.

It is desirable that at future meetings of the Conference the question of astronomical nomenclature should be considered; the practice of using the same names for sidereal and mean time is extremely inconvenient. I have suggested that the sidereal hour should be called a *sid*, or *sider*, and the second a *cron*, so that sidereal time would be indicated by the letters *s*, *m*, and *c*. Some such change is greatly needed, and new names should also be assigned to minutes and seconds of arc.

London, December 1 LATIMER CLARK

The Electric Light for Lighthouses and Ships

The application of the electric light to lighthouses and ships appears to me to be capable of considerable extension by a modification of the apparatus used. In lighthouses the practice is to have a fixed light in the lantern, with an apparatus either catoptric or dioptric, or a combination of both, for the purposes of bringing the rays of light from the arc into a parallel beam and sending them to the horizon. Sometimes, if not generally, this beam is cylindrical, and sweeps round at intervals of time as the combination of lenses and reflectors is rotated.

In the case of ships the head-light is an ordinary arc light, and searchers in use on men-of-war are arc lights set in the focus of a parabolic reflector, and pointed straight at the object it is wished to light up.

The arrangement that I would suggest as partly applicable to lighthouses and fully applicable to ships would be to use a fixed arc-light and large parabolic reflector in combination with a large, light, plane or suitably curved mirror to direct the beam of light, rendered parallel and cylindrical by the parabolic reflector, in any direction by means of this mirror only.

To apply this principle to a lighthouse, this light movable mirror would be placed in the lantern at an angle of something less than 45° with the vertical; the arc light and the fixed parabolic reflector would be placed below, centrally, in the tower; the light would then come from the parabolic reflector on the plane mirror, and so be sent in the required direction.

In using this mirror, where the light has to sweep over an angular area of less than 360°, I would use a to-and-fro motion, so that if the time of each sweep from side to side was 30 seconds of time, then any vessel in the middle line would have the light at this interval, but at any angular distance from the centre line the duration of the flashes would differ until, at the extreme range, two would be seen almost together, with almost 60 seconds interval between them and the next two, the sum of the time of two intervals always being the double of the fixed time for that light, and the difference between two intervals for all positions off the central line would enable the distance from the centre line to be determined by a vessel within the range of the light. An arrangement similar to this would answer for masthead lights for ships, the arc light and parabolic reflector being below deck, a light metal tube, terminating with a lantern to carry the plane mirror, going from the deck up to the required height in front of the foremast; the movement in azimuth of this mirror might be of the same kind as that mentioned for the lighthouse, but a much quicker motion from side to side, through 180° in about five seconds, would then give this time for all points in a straight line ahead, but vary at the sides in the manner already mentioned. As the light plane mirror has only to be moved, a clockwork arrangement would answer perfectly well for this purpose. In rough weather, when the vessel rolled, the light would have a tendency to vary too much in the vertical direction, but it would not be difficult to make the correction by a gravity counterpoise.

For war-ships such an arrangement, but on a more powerful

scale, would answer for a searcher, and the motions could be given by simple mechanical means or by means of electromotors worked from any point. Here the chief working parts of the apparatus would be fully protected, and this would be of the first importance, and the rapidity with which the light could be directed to any point or rendered quite invisible would be a great improvement on the present model, where all has to be exposed.

For forts requiring powerful searchers, and it is easy to see that they might be of great use here, this arrangement is suitable, particularly as the mark, being stationary, is more likely to be struck than in a ship; but the replacing of the plane mirror would be easily effected, and other part of the apparatus of course being quite protected, as in the case of ships.

In the case of a fort in a channel that it was desired to protect, the beam of light from a powerful fixed parabolic reflector could be so truly sent that it could be reflected from mirrors at a distance, as on the banks of the channel, so as to sweep across close above the level of the water and show the smallest object crossing the illuminated line.

It may be objected that in this second reflection there will be a loss of light, but that loss can be made very small, and there would be positive gain in using a large parabolic mirror in place of the necessarily small and imperfect ones in use in a lantern of a lighthouse or the deck of a vessel. Such a parabolic mirror could be made accurately in sections of very thin glass silvered at the back so as to retain its reflecting powers for an indefinite time; in the case of a lighthouse it might be placed at any point vertically below the lantern, even at the bottom if the tower had a well as large as the intended beam of light. The large mirror above may be also of thin glass silvered in a similar way and with such a slight curvature as might be required to enlarge the beam in any way, and more than one of these mirrors might be used if it was necessary to have a fixed light in one constant direction or for any other purpose. I am not sure if there would be any gain in the power to penetrate fog. In the case of a head-light, there would be certainly, from the collection of light into a beam instead of the naked arc; but whether a light such as the very small point that forms the arc including the incandescent carbon ceases to affect the eye in fog sooner than the same intrinsic light seen as a surface must only be settled by experiment on a proper scale.

Ealing, December 5 A. AINSLIE COMMON

Natural Science in Schools

IN the interesting discussion which has recently been carried on in your pages on the teaching of natural science in schools, not much has been said about the text-books which are, or should be, read. So long as the present system of teaching a single branch of natural science continues, and until the method recommended by Prof. Armstrong is adopted, it is clear that great care should be exercised in the choice of a good text-book on the particular subject selected. Even when it is found possible to teach science in the form of physiography, or *Naturkunde*, there will doubtless be many boys in the large schools who, having thus obtained a great amount of most valuable general knowledge and a wider view of the aims of science than is possible under the present system, will wish to carry on their studies in a particular direction. Taking chemistry, as the subject with which I am most familiar, and which at present is perhaps more widely taught than any other branch of science, it may be said that there should be no difficulty at all in selecting a suitable book. It is true that the number of text-book of chemistry is extremely large, and it is also true that there are a few books, written by men of wide knowledge and long experience in teaching, which are well adapted to the purpose in view. But it is, unfortunately, equally true that there are many text-books which are either untrustworthy or are badly arranged, or which contain little more than a bare collection of dry facts, and it is to be feared that some of these not unfrequently find their way into schools. Doubtless most teachers of chemistry will agree with Prof. Armstrong that the educational value of a course of instruction dealing merely with the methods of preparation and the properties of a number of elements and compounds is extremely small, because the faculty of reasoning from observation is not thereby developed. It will also, I think, be generally admitted that "it is of great importance that the meaning of the terms 'equivalent,' 'atomic weight,' 'molecular weight,' should be thoroughly grasped at an early stage." But it would perhaps be better that students should remain in complete ignorance of the meaning of these terms than that they should obtain such erroneous and illogical notions of atoms and molecules as are contained in some of the text-books. One of these books, which in 1880 had passed through no less than fifteen editions, and which appears therefore to be largely read, and which is advertised as being recommended by the head-masters of certain schools, contains the following remarkable statements:—

"Chemists *assume* that the elementary bodies are built up of infinitely small particles, which they call atoms; they further *assume* that these atoms, with few exceptions, are all of the same size. . . The exceptions are phosphorus and arsenic, whose atoms are believed to be half the usual size; and zinc, cadmium, and mercury, whose atoms are double the size." (The italics are the author's.) To the uninitiated it might appear strange to argue about the relative sizes of infinitely small particles.

Again:—"*All molecules are of the same size;* for the law of Ampère, which most chemists now accept, states that 'all gases and vapours contain the same number of molecules within the same volume.'"

Most of the errors contained in these statements are of course due to a misapprehension of the meaning of Avogadro's (Ampère's) law. It is not very easy to give an average student a clear conception of the fundamental generalisations and theories by means of which chemists have been able to determine the most probable relative atomic weights of the elements. To do this, it is first of all necessary to induce the student to think and reason for himself, and it seems to be much easier for most people to repeat a thing from memory than to understand it. But when the student's memory has already been stocked with such illogical statements as those quoted above, the difficulty is very greatly enhanced. SYDNEY YOUNG

The Edible Bird's-Nest

THE nature of the material from which the edible bird's-nest is formed has been long the subject of controversy. It is very gratifying to find from Mr. Layard's letter, published in last week's NATURE (p. 82), that a reconciliation of the various views is possible. Most writers support the theory that the substance is secreted in some way by the bird, though they differ as to the manner. Sir E. Horne, in a paper published in the *Phil. Trans.*, 1817, suggests certain gastric glands as the active ones. Bernstein, forty years later, points to the prominence in the nest-building season of certain salivary glands which form cushions by the sides of the bird's tongue, and suggests that these secrete the material. On the other hand, there are advocates of the view that the nest is constructed of certain vegetable matter found by the birds in the caves where the nests are built, and agglutinated by them by a buccal or salivary secretion.

Through the kindness of Prof Michael Foster I have been enabled to make some observations on the chemical nature of the material of the nests used for soup at the recent Health Exhibition, and from my experiments I have come to the conclusion that this is a substance resembling very closely the *mucin* described by Eichwald, Obolensky, and other writers, as forming the chief constituent of the mucous secretion of all animals and of the tissues of *Helix pomatia*, &c. It shows under the microscope scarcely any structure, but is laminated, shells splitting off easily in two directions. It contains here and there certain bodies resembling the cells of squamous epithelium. It is insoluble in either cold or warm water, but swells up in either, forming a gelatinous-looking mass; in both lime-water and baryta-water it is slowly dissolved, and the reactions of the solution differ very little from those described by the writers named as those of mucin. It resembles this body also in its behaviour when heated with acids, alkalies, and the different digestive ferments. The solution in lime-water contained a little debris, which proved to consist largely of pieces of feathers, with a little adherent amorphous matter. With the exception of certain microscopic particles among this, I could not get any evidence of the presence of vegetable matter in the nest substance. Indeed all the experiments I have described point certainly to the absence of anything but a glandular secretion.

The so-called South Plant of Egyptian Art

THE identification of the original source of any conventionalised artistic form is always, I think, worth notice. It will probably interest many readers of NATURE to draw their attention to a short but instructive piece of work of this kind which Prof. Julius Lange has communicated to the Royal Academy of Copenhagen (*Bull.*, 1884, pp. 109-114). I am indebted to Mr. Liden, one of our garden staff at Kew, for a translation of the paper from the original Danish. I have freely condensed the details.

There is a well-known Egyptian symbol which represents both Northern and Southern Egypt. The northern symbol is admitted to represent the stem and head of the Papyrus. But the southern symbol has not hitherto been identified with any certainty. It has a lily-like form, and has been generally referred to the Lotus (*Nymphæa*), an identification which Prof. Lange thinks quite inadmissible, as the conventionalised treatment of this plant in Egyptian art is quite different.

The twin-symbol combining in a kind of knot the north and south plants is commonly found inscribed on the thrones of statues of Egyptian kings. In the later examples the south plant has the form of a flower with three divisions of the perianth depicted (implying that it was either five- or six-parted), and a definite flower-stalk. In one case Prof. Lange met with an example where the flower was separated from its stalk by some transverse carved lines.

Prof. Lange has, however, recently examined a diorite statue of King Chefren, which gives the symbol in a more primitive form. He finds that the supposed flower passes imperceptibly into the stalk, and that the apparent perianth segments are really distinct parts which are tied together by indications of ligatures. Without then arriving at any definite conclusion, he is content to point out the resemblance of the south symbol in this form to the palm-capitals of the Ptolemaic period. In these the leaves of the date are disposed round the body of the capital, and the junction of this with the column is indicated by transverse bands, the conventional representations of the ligatures which would hold the leaves together and in their places. As the date, according to Alphonse de Candolle ("L'Origine des Plantes cultivées," p. 240) has existed from prehistoric times in the dry and hot zone from Senegal to the basin of the Indus, between lat. 15° and 30°, a more characteristic plant as the symbol of Southern Egypt can hardly have been pitched upon.

W. T. THISELTON DYER

Earthworms

I SEE, in your issue of October 9 (vol. xxx. p. 570), an interesting communication entitled "A Gigantic Earthworm," in which the writer refers to worms of large size being fairly common in parts of Cape Colony. I may mention that here in Ceylon it is not an infrequent sight to see two or three of these big worms in the same day, after showers, though I would not pronounce them to be exactly common. I have seen some fully four feet in length, and about the thickness of one's little finger. They are of a pale slaty-bluish colour, and appear, on close examination, to have faint prismatic colours over parts of the body. These worms are seemingly not confined to particular soils or altitudes, as I have met with them at elevations of from 2000 to 4000 feet above the sea. Owing to their seeming inertness of body, the *lob-worms*—as I have frequently heard them called—soon fall an easy prey to swarms of small red and black ants, that attack the victim as it lies on the ground.

Passing from large to small, I may mention a curious earthworm that I found to be very common in North Borneo. The chief peculiarity about this worm is the size of its "cast," this being about four inches high by one inch and a half across the top, which is made cup-shaped or with a marked depression, for the purpose, I believe, of catching water. The stem—if I may apply the word—of the "cast" is about an inch in diameter, strongly built of rows of earthy matter laid circumferentially, widening towards the top into a lip that forms the side of the cup. Sometimes a leaf may have fallen on the "cast" in the course of erection, and this is at once built over, so that part of the "cast" may be seen above and part below. The worm itself is very small, and hard to secure. I have found the only method of catching them was to suddenly break off a fresh "cast," when one could get a glance of the worm as it rapidly withdrew into the ground. It is of a fleshy red colour, and about the thickness of the stem of a crow-quill pen, but I do not know how long, as I never succeeded in extracting a whole worm from its burrow. The "casts" are very numerous, and weigh, I should think, quite an ounce each, and are to be met with both in the forest—as well as in gardens—and cultivated land. I also found them close to the banks of rivers that were sufficiently near the sea to be considerably impregnated with salt, so that I conclude from this that salt water is not destructive, at least to this species.

FREDERICK LEWIS

Bogawantalawa, Ceylon, November 5

Injuries caused by Lightning in Africa

IT is a remarkable fact that in all the publications relating to Africa we so seldom come across accounts of injuries caused by lightning. Some travellers—those of the German Loango Expedition of 1873-76 for example—even distinctly report that, notwithstanding the extreme frequency of lightning in Africa, cases of damage inflicted by it are almost unheard of. During my own stay on the Congo, though I was eagerly on the look-out for instances of this kind, I did not succeed in authenticating a single case of injury due to the electric fluid. There was indeed a vague rumour among the natives of a man in some village having been struck dead and a "tshimbek" burnt down by lightning, but I could find no eye-witnesses of the fact; and all the time I was in Africa I never saw a tree or other object which showed any signs of having been struck by lightning. The only case of which I obtained any authentic report was that the coal-magazine of the French factory at Banana was burnt down in consequence of a lightning-stroke in March 1882. I have been recently informed, however, that just a year after the destruction of the French coal-magazine, the large gin-store of the Dutch factory at Banana was similarly destroyed, a flash of lightning having kindled a great fire there which lasted four days. As a result of these two accidents following so close on one another in the same locality, lightning-conductors are now being set up at Banana, and the International Association of the Congo has had conductors fixed on all the magazines at Vivi.

I find in Dr. Pogge's journals, which I am now preparing for publication, an instance, witnessed by that traveller himself, of a man being killed by lightning. As far as my own researches go, I find scarcely any literature concerning the use of lightning-rods or the frequency of accidents from lightning in the tropics: and if any of your readers would communicate to the columns of NATURE any information relating to this subject which they may have gained by a residence in those regions, they would render a great service to meteorological science.

Hamburg, November 29 VON DANCKELMAN

The Northernmost Extremity of Europe

YOUR correspondent, Mr. Mattieu Williams, says, on p. 54 that Tonsberg "is admitted by all as a high authority" on Norway. May I be permitted to ask who these "*all*" are? I knew this gentleman very well, and he never claimed the least *geographical* authority for a faulty and crude "Guide for Tourists," which is all that his work is. I beg to refer your correspondent to the preface, where the author himself says that, for reasons explained, it has many faults. To set Tonsberg up as a *geographical* authority would indeed be an insult to Norwegian geographers. Your correspondent further says that he saw with his own eyes, ten years ago, that Knivskjærodden jutted further north than the North Cape. Had I happened to meet him before he started on his excursion, I, then but a school-boy, could have informed him of this startling fact. What I said was, that we had assumed it, but it had only been *proved* by measurements this summer. That was all. As regards the *height* of the promontories on the coast of Arctic Norway, I am sorry to have to repeat my contradiction that there is no single one which is higher than the North Cape. Your correspondent again quotes Tönsberg. If quoting this "high authority" at all, the statement should be correct. Your readers are informed that this guide-book says that Sværholtklubben "is *twenty-four* Norwegian (why *Norsk*? if Norwegian it should be *Norske*) feet higher than the North Cape." Tönsberg says nothing of the kind. What he says is simply that it is *upwards of* (*henved*) 1000 feet, and from this vague guess your correspondent evolves a fresh discovery and figures. Had he taken the trouble to consult the poorest of our geographies, he would have learned that the North Cape is *indisputably* the highest headland in Finmarken. His concluding statement that there are a dozen others is merely an imaginative one.

As a foreigner, I cannot refrain from remarking that it seems strange to me that, because a man has paid a few weeks' visit to Norway, and even "halted in front of the North Cape for half an hour," he can claim to have become an authority on all scientific and other matters connected with that country among a nation which can boast of such distinguished explorers and *savants* as the English. The Scandinavian Club

Our Future Clocks and Watches

IN connection with the indication of universal time by our future timepieces, I venture to suggest that the hours should be contained in one circle; but, instead of being numbered consecutively from 1 to 24, they might be arranged in Roman numerals, as at present, and if figured alternately would be almost, if not quite, as distinct as on the faces of our present style of clocks. Thus, the hours 2, 4, 6, &c., would be shown in figures, but the intermediate or odd hours, as 11, 13, 15, &c., would be more advantageously distinguished by an arrow-head or circular dot.

As regards the striking of the hours by our public and private clocks, they might strike up to twelve, as at present; the suggestion of your correspondent "R. B." (NATURE, vol. xxxi. p. 80), that they should not strike any number above six, appears to me as objectionable as if they struck up to twenty-four; but to distinguish between the afternoon and morning hours, the hours from thirteen to twenty-four might be distinguished by being preceded by two strokes in rapid succession either upon the bell which strikes the hours, or, preferably, upon a bell of a different tone. Leyton, Essex

Singular Optical Phenomenon

ON the night of November 28, at about six in the evening, I went to the window to look at the moon, and saw, as it were, a *second* moon behind the other. The effect was so like what one sometimes experiences from suddenly going out of a very light room, or other causes, that at the time I fancied it was only a defect in my sight. On going into my son's room an hour afterwards he said: "If something is not gone wrong with my eyes, there are two moons out to night." On this I went out again, but saw only the one moon as usual. Later in the evening a young girl who had been meeting a friend at the Montreux train, said her friend had said the moon looked *queer* all the while she was in the train. The night previous a pretty severe shock of earthquake occurred in Geneva and Lausanne, and a few hours after we had observed the moon on the 28th, a very violent gale and snowstorm took place, and lasted for about six or eight hours. I am not scientific enough to know whether the "rosy glow," reported on November 28 by Mr. Leslie of Southampton, can have any connection with this, or whether my letter will interest your readers. Vevey, Canton de Vaud, December 6

The Aurora Borealis

WITH the view of making the Norwegian catalogue of the aurora borealis, at which I am now working, as complete as possible, I take the liberty of asking meteorological societies which are in possession of journals supplied by those who have navigated *Norwegian waters*, to be good enough to place within my reach a copy of the observations which these journals contain respecting the aurora borealis seen near *the coasts of Norway or in their neighbourhood*. I should also be equally grateful for all information with regard to other unpublished observations of auroras of Norway, which may perhaps be found in the archives of meteorological institutes. SOPHUS TROMHOLT

The Meteorological Institute of Christiania, November 19

THE UNITED STATES FISH COMMISSION

IN the year 1871 the Congress of the United States had its attention directed to the alarming decrease in the abundance of its east coast food fishes, and appointed a Commission to investigate the matter, with the idea of preventing the decrease. Prof. Spencer F. Baird, then Assistant Secretary of the Smithsonian Institution, was appointed at the head of this Commission, and in the early summer of 1871, with a small but efficient corps of naturalists, he established himself upon the southern coast of New England at a place called Wood's Holl. Among the most noted of the members of that party were A. E. Verrill, S. J. Smith, and Sanderson Smith, all of whom have remained with the Commission every summer since its foundation. The first work of the Commission was to investigate the fauna, which then was comparatively unknown to science. In this way the food-supply of the food fishes and the food fishes near shore were carefully studied. During this one summer the fauna of this region was so carefully studied specifically that few new species have since been discovered. The main results were set forth in a very extensive report upon the invertebrate animals of Vineyard Sound by Profs. Verrill and Smith, and published in the first Fish Commission Report. In the summer of 1872 Eastport, Maine, was chosen as the station, and here the same systematic study was carried on with the addition of some dredging work done in shallow water with small boats. The summer of 1873 was spent at Portland, Maine; 1874 at Noank, Conn.; 1875 at Wood's Holl again; and 1876 being Centennial year, there was no summer station, but the energies of the Commission were exerted upon the Centennial Exhibition at Philadelphia. In 1877 a part of the year was spent at Halifax, Nova Scotia, arranging a fisheries treaty, and the remainder at Salem, Mass. The head-quarters for the summer of 1878 were at Gloucester, Mass. Up to this time, and, in fact, until 1880, the Fish Commission had carried on all its off-shore work in steamers placed at its disposal through the courtesy of the Coast Survey and Navy Department, but had owned no boat of its own with the exception of small sailing-boats and a steam-launch in which the shore work could be done. Thus under a decided disadvantage, it would hardly be expected that a great amount of work could be carefully done; but, notwithstanding this, a large part of the Gulf of Maine was very carefully explored, under the direction of the Fish Commission. During the years 1878 and 1879 the fishermen of Gloucester very materially aided the Commission in its work of investigating the fauna of the shallower water of New England by preserving such specimens of animals as they happened to meet on their fishing trips. Scores of animals new to the American waters were taken from the fishing-banks by these fishermen, and the importance of their work should not be under-estimated.

As yet the Fish Commission had done little practical work in its marine departments. It was for practical work that the Commission was established, and all its scientific work had some practical object in view. In the winter of 1878 and 1879 the Commission began important experiments upon the hatching of deep-water fish, but more especially cod. When America was first discovered, cod were found on all its shores in great abundance, and from this abundance the headland of Cape Cod received its name. As white men became more numerous on the shore and cities began to grow, the fish began gradually to decrease in number and be driven off into deep water because of the impure condition of the water. Now, in places where fifty years ago cod could be caught from any point of rocks, it is a rare thing indeed to catch this fish within several miles of shore. Men, who not many years ago could anchor a boat within a few rods of shore and catch fish in large quantities, are now obliged to visit the more remote ledges several miles from shore, and be satisfied with a light catch. Even in the deep water they are becoming scarcer. It was with the hopes of finding some remedy for this decrease that in 1878 and 1879 Prof. Baird began experiments upon artificially hatching these fish. Millions of eggs are laid where few come to maturity, the larger part being destroyed before they are hatched from the egg. Thus, if the eggs could be hatched and the

young placed in the water only when they are old enough to partially take care of themselves, the proportion that would arrive at maturity would be vastly increased. By constant work at hatching these fish it was thought that much practical good might result. Many difficulties stood in the way, the most important being that the eggs floated and clogged the overflow screen. After much experimenting this was overcome. It was found, however, that the place chosen, Gloucester, was by no means fitted for the work because of impure water and extreme cold; but the object of the present work was merely experimental, and it mattered little whether the fish which were hatched lived after being placed in the water. Several millions of young cod were thus successfully hatched and placed in the waters of Gloucester Harbour, but, because of the impurity of these waters, it was hardly expected that the fish would be heard of again. But early in the spring of 1882 reports began to be circulated that young codfish of the deep-sea species (*Gadus morrhua*) were abundant in Gloucester Harbour. Subsequent investigation proved this report to be true. Since the cod first left our coast they have not been found in the Massachusetts harbours in any abundance, but at this time, even in the impure docks of Gloucester Harbour, it was not infrequent for boys fishing for perch and flounders to catch young cod. Several generations were distinguishable, and as there is but one other place where a similar abundance is reported, there is every reason to believe that they are Fish Commission cod, and that the other school is but an offshoot of the original group which was placed in Gloucester Harbour. It is, of course, expected that they will migrate, in time, to purer, cooler waters outside. There are fishermen now who are making good catches of these cod in the harbour itself—a thing unprecedented in late years. Thus the experiments, though primarily successful, have met with an additional success which was not in the least expected. Gloucester not being naturally suited for hatching cod, the Commission has begun the building of extensive hatching-houses at Wood's Holl, where in a few years artificial hatching of deep-sea fish will be carried on extensively. While at Gloucester the members of the Commission made extensive inquiries into the statistics of American fisheries, and complete reports upon the results have been published in the Fish Commission publications.

The summer of 1879 was spent at another large fishing port, Provincetown, Mass., where additional studies of the fishing apparatus were carried on. In 1880 the Commission was at Newport, Rhode Island; 1881, 1882, 1883, and 1884 were spent at Wood's Holl, Mass., which has been chosen as the permanent summer station of the Commission, because of the many natural advantages offered by the location. At present extensive buildings are in progress at this station. A large hotel for the use of the Fish Commission *employés* is already built, and was for the first time occupied during the past summer. On one side of this hotel the new laboratory and hatching-station is being built. It will be a very large affair, the lower story being intended for use as a hatching-room, the upper for a laboratory in which the scientific work will be done. In the cellar there are some large stone-walled tanks which will have direct connection with the outside water. A steam pumping-station will supply water to the aquaria and hatching-tanks. In front of these buildings is a large breakwater wall which will serve the purpose of a wharf for the larger vessels, and will also form a harbour for the smaller boats. It is expected that actual operations in fish-hatching at this station will begin in the spring of 1886, and that after that time each year millions of young fish will be sent out from the station to all parts of the New England coast and placed in the water to take care of themselves. It is hoped by these means to at least make an appreciable difference in the number of cod after years of work, and in part make up for the decrease. In the laboratory not only the regular *employés* of the Fish Commission will be allowed to work, but in the future a limited number of general students will be admitted to a table in the laboratory. By special arrangement with several of the leading American colleges, two students from each will be allowed to work each year in the new laboratory. This will be a chance that will be eagerly sought after because of the great advantages for study offered at the station. Under these improved advantages, it is expected that much better work will be done in the future than has been done in the past, when all the work had to be carried on in an old shed-like building poorly fitted for the work.

In 1880 an appropriation was obtained from Congress for the purpose of building a steamer, which was to serve as a floating shad-hatching station to work in the Chesapeake. This was the first large steamer owned by the Commission, and was named the *Fish-Hawk*. Although intended for shad-hatching, at the end of each shad-hatching season she proceeded to the summer station to engage in dredging. On account of her shallow build she was not fitted for dredging, and the Fish Commission was greatly inconvenienced while she was used for this purpose. The remarkable results obtained by this steamer on the Gulf Stream slopes have long since become known to the scientific world. Several hundred species were found which were new to American waters.

It was not long before the Fish Commission became convinced of the necessity of having a new steamer in which they could go to sea at any time, and one which was perfectly adapted for deep-sea dredging. Accordingly, in 1883, the *Albatross*, a 1000-ton iron steamer, 234 feet long and drawing 12 feet of water, was launched and immediately began work. That she is very nearly perfect in all respects, both in build and outfit, has been proved by her two years of nearly steady work. She is without doubt the most perfect dredging-steamer ever owned by any Government, and she is achieving the most remarkable results.

In the spring of 1879 a new fish, the tile-fish (*Lopholatilus chamælionticeps*), was found in abundance in the deep water south of New England, which promised to become an addition to our east coast food-supply. It was abundant and had a fine flavour. In the early spring of 1882 it was found dead in immense numbers on the surface just above the places where it was found in such abundance. In the official report it is estimated that there were at least 71,936,000 dead fish, of an average weight of ten pounds each, in an area of 5620 square statute miles. This estimate was arrived at by taking the largest trustworthy report of the numbers of dead fish given by the numerous captains and dividing it by 400, thus allowing that there was only one fish where 400 were reported to be. This wholesale destruction attracted much attention at the time, and the Fish Commission has since made a careful study of the subject, and although many trials have been made, not a single tile-fish has ever been taken. A few other species of animals have also disappeared from the same bank, and it is the theory that a cold wave of water from the inlying shallower region was driven across the warm bank inhabited by these fish by the strong northerly winds which prevailed at the time. The tile-fish being naturally a delicate fish, was killed by this sudden change of temperature, while less delicate animals survived. Whether they are entirely extinct or not cannot be told. Certain it is that, although many expeditions have been sent out and days spent in search of this fish, not a single specimen has been taken since that great mass of dead fish were found covering an immense area off the American shore. It is by far the most interesting problem as yet studied by the Fish Commission. An interesting history of this fish is given by Captain Collins in the Annual Report of the U.S. Commissioner of Fish and Fisheries for 1882, pp. 237-292, with a figure of the

fish and a map showing the position of the banks and the area covered by the dead fish.

In addition to this branch of the Fish Commission's work, it has been doing a very important service to the country by hatching shad and salmon, and partially re-stocking rivers with these fish. By introducing the German carp to America a work of great economic importance was achieved, and the large number of carp-ponds in America shows the popularity of this new fish. In connection with State Fish Commissions much work is being done, which is of great importance. In every State of the Union there is now a more or less important State Fish Commission, and nearly all have been started since the National Commission, which may be considered to be the father of them all. For several years naturalists of the Fish Commission have been studying the oyster problem, with the hope of in some way protecting them from their natural enemies and preventing their decrease. Under the direction of Mr. J. A. Ryder important experiments upon artificial oyster-farming have attained a marked degree of success, and within a comparatively few years it may be expected that oyster-culture in America will be revolutionised. There are at present experiments in progress upon the transplantation of certain desirable shell-fish from the east coast to the west coast of America. Owing to the extreme difference in character between the water of the two coasts, it is doubtful if these experiments will succeed.

For the purpose of studying the economic problems it is necessary that men be sent to different parts of the American coast, and these men are always instructed to study the fauna and make collections. These collections are all, after careful study by the Fish Commission naturalists, turned over to the United States National Museum, and in this way her zoological collections are vastly increased. The collections made by the Fish Commission steamers are of vast scientific importance, and they greatly add to the interest and value of the zoological branch of the National Museum collection. It is also the plan of the Fish Commission to distribute sets of duplicates from their collections to the different Museums of the country. Nearly 200 such sets have already been distributed, and special sets are made up for exchange with foreign Museums. It has been the policy of the Commission to carefully study American fisheries and the apparatus in use both in this country and abroad, and by this means find out the most improved apparatus and have it adopted in America. It was with this object in view that complete sets of American apparatus were sent to the Exhibitions held at Berlin and London, and that experts were sent to study the foreign exhibits. Already the effects of these studies are being felt in America, and American fishermen, having learned in the past to respect the Commission's advice, are beginning to adopt needed reforms in vessels and outfit. It is hoped that the American exhibits had some similar effect upon the fisheries of other nations.

The Fish Commission's work in its original conception was really the solution of practical economic problems, and it has in the main adhered to this idea. Hence its scientific work has been mainly upon animals which are in some way connected with such problems, the work in very deep-sea dredging being an exceptional but natural deviation from the rather uninteresting study of the shallow fishing-grounds to the rich field of deep-sea research. As this work can be carried on in addition to and without interfering with the regular work of the Commission, there is no chance for complaint. To the scientific world it is very important that this is the case. Dealing with the problems that it has, the natural history work of the Fish Commission has, of necessity, been mainly of a systematic character, dealing with species and their distribution more than with problems of anatomy, embryology, and histology. But there has been also much embryological work, that of Mr. Ryder upon certain economic fish and the oyster being of most importance. In addition to this natural history work, there has been the gathering together of complete collections of all apparatus used in connection with the fisheries, which have been placed in the National Museum. At some future time they will possess an immense scientific value.

The scientific and important practical results of the Commission's work are mainly set forth in the publications of the Fish Commission or the National Museum, but some of the monographs, and also synopses of species, which require better plates than the Government publications ordinarily contain, or need to be published in haste, are printed in some other publications. The Commission publishes an Annual Bulletin and an Annual Report. The former is printed in parts, a few pages at a time, and sent to scientific men as soon as published, and afterwards gathered into volumes. Four have been printed up to date, and they contain miscellaneous articles, many of considerable scientific importance. The Report is published annually, and contains the larger reports upon different questions and general monographs of groups of animals. There are nine volumes already published, and they cover the years of the Commission's work up to 1881. Many of the reports contain articles of great importance to the scientific world.

RALPH S. TARR

THE INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND

A GREAT amount of valuable scientific work, of a special character, is done by the various engineering institutions of the country; and much of the progress latterly made in the practical applications of science to mechanical operations, and also in the advancement of those sciences which bear most directly upon engineering work, is largely due to the growth of these institutions. The principal one—that of the Institution of Civil Engineers—may be regarded as the parent institution, not only by reason of its age, but also because of its high standing and the quality of its work. The Institution of Civil Engineers has contributed, in a very important degree, towards transforming engineering from the position of a "base mechanical" calling into one which ranks high among learned and scientific professions.

The great success and usefulness of the Institution of Civil Engineers has gradually led to its work becoming more and more differentiated, and to certain special branches of it being taken up by other institutions that have been formed for the purpose. We thus find the Institutions of Mechanical Engineers, Telegraph Engineers, Naval Architects (in which marine engineers are included), the Iron and Steel Institute, and others. All of these institutions are in a prosperous condition, and enrol a large number of new members every year. They have been most successful, without exception, both professionally and scientifically. While, on the one hand, they have benefited their members by collecting papers and providing opportunities of discussion upon points of vital interest to them in the pursuit of their various callings, they have also, on the other hand, carried scientific investigation forward in directions which would otherwise have been much neglected. The field of science—and particularly the inductive side of it—has been greatly extended by the able and thorough—though often unobtrusive—work which has been done by the engineering institutions.

It is not in the metropolis alone, however, that such institutions are now to be found. They supply too universal a want to admit of being centred in any one part of the country. We have just received from Glasgow the twenty-seventh annual volume of the *Transactions* of a well-known and excellent institution which exists in that city, viz. that of the Engineers and Shipbuilders in

Scotland. This Institution is not restricted to the marine or any other special branch of engineering, but includes among its members civil and mechanical engineers of all classes, metallurgists, marine engineers, and shipbuilders. Its published volumes of *Transactions* usually contain papers of a varied and instructive character, and very valuable communications from some of the most eminent Clyde engineers are to be found in them. The importance of this Institution may be judged of by the fact that the number of its members, associates, and graduates amounts to 581.

The volume of *Transactions* just issued contains papers and discussions upon the properties of the compound engine, the stability of ships, screw piles, the testing of turbines, cable tramways, and other subjects. There is also a Presidential Address, delivered by the President, Mr. James Reid, of the Springburn Locomotive Works. Mr. Reid reviews briefly many of the latest engineering achievements that have been recorded, or that are being attempted. He refers to railway operations in this country and abroad, tramways, steam-shipping, docks, harbours, canals, bridges, hydraulic and electrical machinery, gas, and smoke combustion. Where the range of subjects is so varied and extensive, the briefest references are usually of course all that are possible.

Mr. Reid points out, with regard to railway traffic, the beneficial results of lower fares and other increased facilities in not only wonderfully augmenting the volume of third-class traffic, but also in adding, upon the whole, to the receipts of the railway companies. "As the downward movement of classes is still continuing, the outcome will most likely be a general reduction of the number of classes to two—nominally first and third, but practically first and second." The railway companies in this country yet have a most useful work to do in circulating food-supplies. The Fish League have had refrigerator cars constructed, which are working between the Scotch ports and London; and this small commencement is capable of a very large and urgently-needed development. A new departure in locomotive practice has been taken by M. Anatole Mallet in France, and by Mr. F. W. Webb in England, by compounding the engines. The results thus obtained are stated to be very satisfactory, although the maximum economy that is practically possible can of course only be obtained by steam-jacketing the cylinder, or by the use of superheated steam.

The advances that have recently been made in steam-shipping are referred to. The fastest voyage made by any steamer prior to October 23, 1883, was that of the *Alaska*, in which she ran 2784 miles, between Queenstown and New York, in 6 days, 21 hours, and 40 minutes. Mr. Reid says that this is equivalent to a mean speed of 17 miles per hour; but he speaks of miles in connection with these figures as though he were dealing with ordinary statute miles. The figures given really relate, however, to knots, or nautical miles, so that the speed of the *Alaska* upon the voyage in question was at the rate of over 19½ miles per hour. Mr. Reid also says that at an average speed of 19¼ miles per hour the Atlantic might be traversed in six days. The average speed requisite for crossing the Atlantic in six days is about 19⅓ knots, or 22½ miles, per hour, a speed which nearly amounts to that of many ordinary railway trains.

The performance of the *Alaska*, which Mr. Reid refers to, has been much exceeded during the present year by two Atlantic liners, the *Oregon* and the *America*. The *Oregon* has crossed the Atlantic in less than 6 days, 10 hours, thus beating the *Alaska* by nearly half a day. The *Umbria* and *Etruria*, the new vessels of the Cunard Company, are expected to beat the *Oregon* by about as much as the latter beat the *Alaska*. The *Umbria* is said to have attained, upon the measured mile, a mean speed of 20½ knots, or nearly 24 miles per hour. It is possible that she may succeed in crossing the Atlantic in six days.

Passing from the wonderful strides thus making in steam-shipping, the President calls attention to the chief of the large canal schemes which are now before the world, such as the Panama Canal—which the indomitable energy of M. de Lesseps appears likely to bring to successful completion—an independent canal across the Isthmus of Suez, and the Manchester Ship Canal. It is surprising, however, that, while referring to these various means for facilitating transit across the ocean, and also to the Channel Tunnel, Mr. Reid omits to notice the ship-railway scheme of the American engineer, Capt. J. B. Eads, C.E., which has now been for some time before the engineering world, and has received the approval of some of the most eminent authorities.

The principal papers contained in the volume of *Transactions* under notice are those upon the compound engine viewed in its economical aspect, by Mr. R. L. Weighton; upon the stability of ships at launching, by Mr. J. H. Biles; and on approximation to curves of stability from data for known ships, by Messrs. F. P. Purvis and B. Kindermann. Mr. Weighton's paper gives a clear and able explanation of some of those properties of the compound engine which affect its economical working; and while there is nothing novel or recondite in it, and it is somewhat amateurish in style, it is of value in keeping before the minds of engineers points of fundamental importance which it is well for them to think precisely and frequently about; and it did good service in causing one of the longest and most interesting discussions which took place during last year's meetings. We dissent entirely from an opinion expressed by one of the speakers, that "papers brought before an Institution of this kind should either expound some new theory, contain some novelty, or bring before them some important addition to the mechanical details of any machine." An exclusive striving after mere originality is not an unmixed good; besides which, one of the greatest advantages of such institutions as that of the Engineers and Shipbuilders in Scotland is that the members become familiarised by papers and discussions which are even of a commonplace type with what is already known and thought by the most capable men upon subjects that all engineers require to thoroughly master. It is not novel points nor original conceptions only which are of value to the rank and file of members; a still more potent cause of good is to be found in the educating and informing influence which is exerted by well-established scientific ideas and recorded experience being frequently discussed, and by the constant and ready reference to fundamental and accepted principles which this involves.

The paper on the stability of ships at launching is accompanied by curves for various types of steamer at launching-draught, and advocates constructing such curves, as a rule, before launching ships. It is well worth reading, as it, and the discussion upon it, show how diverse and inconsistent though, on the whole, vague are the views held by many shipbuilders, both upon the necessity for ascertaining the precise degree of stability possessed by a ship, and also as to the sufficiency of a given amount of stability for purposes of safety. The author is somewhat ambiguous and inaccurate in his definitions of such terms as "stability," "stiffness," &c., and inconsistent and loose in his use of them: but this appears to be a common fault with technical writers upon naval architecture, as was pointed out by Prof. Osborne Reynolds at the British Association meetings of last year. For instance it is stated in the paper under consideration that "the kind of stability which is required at launching is stiffness," and "the question of stability at launching appears therefore to reduce itself to one of stiffness,"—stiffness being represented by the metacentric height, which measures the force required to incline a given vessel through small angles from a position of rest in still water. Yet the author goes on to say that "our only safe guide is the

complete investigation of the stability of a ship at angles considerably beyond those to which the metacentric height is a fair measure of the stiffness." He also speaks of the "stability of a ship up to 60° of inclination." This is a strange although common misuse of the term "stability." Stability only exists at a position of stable equilibrium, and what is really meant by the above-quoted sentence is not stability at large angles of inclination, but *righting force*.

The other paper upon stability, which describes a method of approximation to curves of stability from data for known ships, is interesting in showing how some of the elements of stability vary in a ship with the ratios of draught of water to depth, and depth to breadth; but we cannot regard it as likely to be of much value in practice. The approximations obtained by applying the method are only reliable when the form of the vessel for which the curve of stability is required, and that of the one which is being used for estimating it from, are so related to each other that any section of the one may be obtained by projection from the corresponding one of the other. Differences in form are excessively numerous—almost universal indeed—among ships; and small discrepancies of such a kind often affect stability to an important degree. When vessels are found to belong to what is defined in the paper as a "type-form," the method is applicable, but where no true type-form can be discovered for a particular ship—and this is what usually happens in practice—the only reliable and also the readiest mode of approximation to a curve of stability is to compute by means of Amsler's integrator the true length of a small number of ordinates of the curve.

There are other papers of interest in this volume which are amply deserving of perusal, though we have not space for referring in detail to them. We may note, however, as an indication of the active and enlightened interest taken by Scotch engineers in scientific teaching, that the President of the Institution of Engineers and Shipbuilders in Scotland—in referring at one of the meetings to the endowment of the John Elder Chair of Naval Architecture in Glasgow University, which is filled by Prof. F. Elgar—said that "the Council had agreed, and were morally bound, to support the institution of a lectureship in anticipation of a Chair of Naval Architecture in the University." Mr. Reid further stated that "the Council had agreed to continue the lectureship in connection with the Chair," and he wished it to be known that the original intention was still to be carried out. This is a strong practical proof of the earnestness and wise liberality of Scottish engineers in the matter of scientific and technical education, and it is a policy which cannot fail to largely benefit the district in time to come. It is also one indication, out of many, of the advantages which may confidently be looked for by engineers and scientific men as the natural outcome of such institutions as those we have referred to.

THE EGGS OF MONOTREMES

SPEAKING at the anniversary meeting of the Royal Society in November 1883, Prof. Huxley said:—"It certainly was high time that British science should deal with a problem of the profoundest zoological interest, the materials for the solution of which abound in, and are at the same time confined to, those territories of the Greater Britain which lie on the other side of the globe." These words had reference to the series of investigations which Mr. Caldwell—the first Balfour Student—had then gone to Australia to prosecute with regard to the embryology of the lowest Mammalian forms, the Monotremes and Marsupials.

Somewhat less than a year later, and whilst the British Association was holding its meetings in Montreal, Prof. Moseley, the President of the Biological Section, was enabled to communicate the following brief but suggestive message telegraphed from Australia:—"Caldwell finds Monotremes oviparous; ovum meroblastic." Brief as was the message, it yet, as Prof. Moseley said, contained the most important scientific news which had been communicated to the Association in Canada.

Zoologists will now look forward with deep interest to the publication of Mr. Caldwell's more detailed account of his recent investigations, which have apparently enabled him to confirm so fully what has before been suspected, but never actually proved to be the case.

That Monotremes are oviparous has been maintained by various naturalists for now some sixty years: but up till the present time no sufficient evidence has been brought forward to place the matter beyond dispute, the chief difficulty in elucidating the problem lying in the fact that the two curious groups of animals which alone are placed in the Monotremata inhabit exclusively the Australian region, and hence have been but little studied in their natural habitat.

Though they are closely allied, yet the Ornithorhynchus and Echidna differ markedly from each other in external appearance—the one being adapted to the water, having its feet webbed, and its muzzle of that peculiar shape which has earned for it the name of Duck-billed Platypus, whilst the other is essentially a land animal, feeding on ants which it licks up by means of a long flexible tongue, and having its body covered with sharp spines, much as a hedgehog.

The question of how these animals reared their young, and in what condition the latter were born, has long been a matter of much dispute, and for information we are principally indebted to the memoirs of Home, Meckel, Geoffroy St. Hilaire, and perhaps most of all to Owen; whilst from time to time short notices are to be found in the *Proceedings* of the Zoological Society and the *Journal* of the Linnean Society.

In 1829 Geoffroy St. Hilaire laid a communication before the Royal Academy of Sciences in Paris, entitled "Considérations sur les œufs d'Ornithorinque formant de nouveaux documens pour la question de la classification des Monotrêmes."[1] Herein he stated his opinion that the Monotremes could no longer be admitted amongst the mammals, nor could they be classified with either birds, or reptiles, or fishes, but they must, though including only two groups of animals, be formed into a distinct fifth class among the Vertebrata, which would hence be divided, according to him, into Mammals, Monotremes, Birds, Reptiles, and Fishes.[2] The most interesting part of his paper, from our present point of view, however, consists of a letter which he quotes in full from Prof. Robert E. Grant of London, who describes in some detail the finding by a certain Mr. Holmes, whilst shooting on the banks of the River Hawksburgh in Australia, of a nest of eggs laid by an Ornithorhynchus; the animal was seen to hasten away from a sandy bank and plunge into the water. Examination of the bank led to the discovery of a small burrow, in which, on a rude nest made of twigs, were deposited nine eggs of a peculiar shape and size, which rendered them clearly distinguishable from those of any bird. The eggs, he says, are remarkable "par une forme régulière sphéroïdale oblongue, par une égale largeur à chaque bout; ils ont (mesure anglaise), en longeur de pouce, $1\frac{3}{8}$, et en largeur $0\frac{5}{8}$; la coquille est mince, fragile, légèrement transparente, et d'une couleur uniforme d'un blanc mat; sa surface extérieure, vue à la loupe, présente une texture d'un réseau admirablement réticulé; la matière calcaire a produit les parois blanches de ses innombrable et très-petites cellules, ce qui n'empêche pas que la surface n'en demeure à peu près polie.

[1] *Annales des Sciences Naturelles*, t. xviii. p. 162; also *Bulletin de la Société Philomathique*, t. viii. p. 95.

[2] The same idea is to be found also in Lamarck, *Philosophie Zoologique*, t. i. p. 145. Lamarck adds, further, "Ce ne sont point des mammifères; car ils sont sans mamelles, et très-vraisemblablement ovipares."

Un des œufs était cassé, et j'en ai examiné la surface interne, laquelle m'a paru être aussi formée par un dépôt de très-petits grains de la matière calcaire." He further states that the dimensions and form of these eggs remind him of those of many of the Saurian reptiles and Ophidians; whilst Jarrel, who examined them, came to the conclusion that they differed as much from the eggs of birds as from those of reptiles.

Fig. 1 is copied from a drawing which accompanies the paper of Geoffroy St. Hilaire, and represents its actual size and form.

Of the nine eggs which were discovered in the nest four were brought to England, and of these two found their way to the Manchester Museum, where, Prof. Williamson has kindly informed me—whilst he was curator, from 1835 to 1838—he distinctly remembers

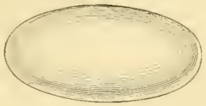

FIG. 1.

their being placed and labelled as "eggs of Duck-billed Platypus."

In 1826 Meckel, of Halle, had published a monograph on *Ornithorhynchus paradoxus* (Leipzig, 1826), wherein he announced the discovery of mammary glands, rudimentary in condition, but still undoubtedly present, and serving for the nutrition of the young; Geoffroy St. Hilaire, who, as before said, was strongly of opinion that the Monotremes could not be included amongst the Mammalia, suggested that the nature of these glands had not been sufficiently studied, and that instead of being mammary they were very probably analogous to those spread out on the flanks of aquatic reptiles, and which served to lubricate the skin; if this were not the case, he further suggested a comparison between them and certain odoriferous glands existing in the neighbourhood of the mammary glands in shrews.[1]

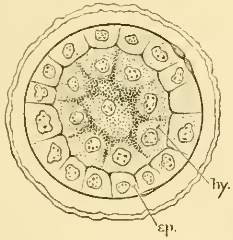

FIG. 2.

To these criticisms Meckel urged in reply the strong argument that they were only known to exist in female Monotremes, the males possessing no such structure, and later still Owen published his account of the "Mammary Glands of *Ornithorhynchus paradoxus*" (*Phil. Trans.* 1832). In this paper also he quotes the following passage from Meckel ("*Ornithorhynchi paradoxi* Anatome," p. 58):—"The difference between the bringing forth of living young and of eggs is really very small, and by no means of an essential nature: birds have accidentally hatched the eggs within the abdomen, and so produced a living fœtus—an occurrence which has been induced by direct experiment; and lastly the generation of the Marsupial animals is very similar to the oviparous mode." Meckel, Owen says, deems it "very probable that as the Ornithorhynchus approaches still nearer than the Marsupials to birds and reptiles, its mode of generation may be in a proportionate degree analogous."

[1] *Proc. Zool. Soc.*, 1833, pp. 28 and 91; also, "Memoir on the Abdominal Glands of Ornithorhynchus, falsely presumed to be mammary, but which secrete, not milk, but mucus, destined for the first nutriment of the young when newly hatched," *Gazette Médicale*, February 18, 1833; also, *Annales des Sciences Naturelles*, tom. lx. p. 457.

Somewhat later Owen published an account of an Ornithorhynchus fœtus,[1] which measured only two inches in length. After describing its external appearance he says, "On the middle line of the upper mandible, and a little anterior to the nostrils, there is a minute fleshy eminence lodged in a slight depression. In the smaller specimen this is surrounded by a discontinuous margin of the *epidermis*, with which substance therefore, and probably (from the circumstance of its being shed) thickened or horny, the caruncle had been covered. It is a structure of which the upper mandible of the adult presents no trace, and is obviously analogous to the horny knob which is observed on the upper mandible in the fœtus of some *birds*. I do not, however, conceive that this structure is necessarily indicative of the mandible's having been applied, under the same circumstances, to overcome a resistance of precisely the same kind as that for which it is designed in the young *birds* which possess it. The shell-breaking knob is found in only a part of the class, and although the similar caruncle in the Ornithorhynchus affords a curious additional affinity to the *Aves*, yet as all

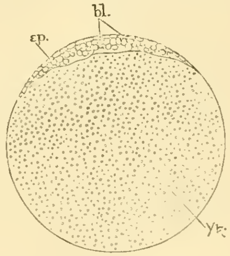

FIG. 3.

the known history of the ovum points strongly to its ovo-viviparous development (see also *Phil. Trans.*, 1834, p. 555), the balance of evidence is still in favour of this theory."

Later still (*Phil. Trans.*, 1865, p. 671) he published a paper on the "Marsupial pouches, mammary glands, and mammary fœtus of the *Echidna hystrix*," wherein he proved that the same caruncle was present in the Echidna fœtus, and further that this was carried about by the mother in a pouch (two being present in each individual, one on either side the middle ventral line), into which opened the mammary glands.

Owen adheres firmly to the opinion that the Monotremes are ovo-viviparous, in which opinion he is supported by the evidence of, amongst others, Sir E. Home (*Phil. Trans.*, 1802, p. 67), whose account is probably the earliest notice of any detail, which was published in England with regard to the internal anatomy of Ornithorhynchus.[2] Home says at the close of his paper, "this animal having no nipples and no regularly formed uterus, led me to examine the female organs in birds to see if there was any analogy between the oviducts in any of that class and the two membranous uteri of this animal;

[1] *Trans Zool. Soc.*, vol. i. p. 222; also *Proc. Zool. Soc.*, 1834, p. 43.

[2] For one of the earliest figures, see Shaw's *Naturalist's Miscellany*, vol. ix. 1799, and for figure of Echidna *vide op. cit.* vol. iii. 1792, under name of *Myrmecophaga aculeata*. Shaw says of Echidna, "It is also a most striking instance of that beautiful gradation so frequently seen in Nature, by which creatures of one tribe or genus approach to those of a very different one. It forms a connecting link between the very distant genera of Hystrix and Myrmecophaga; having the external aspect of the one with the mouth and peculiar generic characters of the other."

but none could be observed, nor would it be easy to explain how an egg could lie in the vagina to receive its shell, as the urine from the bladder must pass directly over it. Finding they had no resemblance to the oviducts in birds, I was led to compare them with the uteri of those lizards which form an egg that is afterwards deposited in a cavity corresponding to the uterus of other animals where it is hatched; which lizards may be therefore called ovo-viviparous, and I find a very close resemblance between them."

There has been, however, a certain amount of direct evidence brought forward beyond that which has been quoted from Geoffroy St. Hilaire's paper to prove that Monotremes are really oviparous, notwithstanding the fact that they nourish their young by means of mammary glands.

Thus a Dr. Nicholson (*Phil. Trans.*, 1865, p. 683), writing to Owen in 1865, informs him that a Platypus had been captured by workmen on the banks of the River Goulburn in Victoria, and had been placed for a night by the gold-receiver of the district, to whom it had been handed over, in a wooden case, and that whilst in confinement it had laid two eggs—white and soft, with no calcareous covering, and about the size of a crow's egg. Dr. Nicholson does not, however, appear to have taken the trouble to examine the eggs at all carefully, and his evidence is rejected by Owen as certainly insufficient to make him doubt that the Monotremes are ovo-viviparous.

Earlier still in Messrs. Lesson and Garnot's "Voyage de la Coquille" (*Zool. Journal*, vol. v.), it is stated that the colonists assured the travellers that Ornithorhynchus was oviparous, whilst a Mr. Murdoch, superintendent of the farms on Emu Plains, said that he himself had seen the eggs, that they were two in number, and the size of a hen's egg.

Again, Dr. Weatherhead (*Proc. Zool. Soc.*, 1832, p. 145) read, before the Zoological Society in 1832, extracts from a letter received by himself from Lieut. Maule in New South Wales, wherein the latter describes in some detail the finding and unearthing of an Ornithorhynchus burrow. The entrance to the latter, he says, is beneath the water, though, after some little distance, the passage rises, and, after a few yards have been traversed, it "branches into two others, which, describing each a circular course to the right and left, unite again in the nest itself, which is a roomy excavation lined with leaves and moss, and situated seldom more than twelve yards from the water or less than two feet below the surface of the earth: several of these nests were with difficulty discovered. No eggs were found in a perfect state, but pieces of a substance resembling egg-shell were picked out of the debris of the nest. In the insides of several Platypi which were shot were found eggs of the size of a musket-ball and downwards, imperfectly formed however, *i.e.* without the hard outer shell, which prevented their preservation."

Dr. Bennett also (*Proc. Zool. Soc.*, 1859, p. 213) investigated the structure of the Monotremes and examined the nest of Platypus, but failed to find traces of eggs.

Lastly, Mr. Patrick Hill, surgeon in the Royal Navy, published in *Trans. Linn. Soc.*, xiii. p. 621, information which had been brought to his notice concerning the Monotremes whilst studying their nature and habits in the district around Sydney. A female specimen was brought to him which had been taken directly from its nest, but which died very soon after being placed in confinement. On opening the body he discovered in the left ovary a round yellow ovum about the size of a small pea and two of smaller size, whilst no trace of ovisac was to be found in the right ovary;[1] but beyond his own investigations he brings forward the evidence of a certain Cookoogong, chief of the Boorah-Boorah tribes, who, as is quaintly remarked in Geoffroy St. Hilaire's article, "ne manquait ni de lumière ni de moralité." This native chief stated that it was a fact well known to their tribe that the animal lays two eggs, about the size, shape, and colour of those of a hen, and that the female sits a considerable time on her eggs in a nest which is always found among the reeds on the surface of the water; the native name for the Platypus, he added, was Mullingong.

The most important part of Mr. Caldwell's communication to the British Association was, however, contained in the two words "ovum meroblastic"; in other words, the ovum of a Monotreme contains, relatively to the pure protoplasm out of which the tissues of the animal will be formed, so much food-yelk that, when segmentation takes place, it is impossible for the egg to segment as a whole, and therefore the two kinds of protoplasm separate, and we find that the Monotreme embryo possesses a yelk-sac, by the gradual absorption of the contained material of which it is nourished during the early stages of development.

The presence of so large an amount of food-yelk thus renders it unnecessary that during this period the tissues of the embryo should enter into such a close relation with the maternal ones as is found to obtain in the rest of the Mammalia, though even amongst the higher members of the latter there are certain signs which point to a former period in their phylogenetic history when they also were possessed of a yelk-sac.

Figs. 2 and 3 represent respectively examples of holoblastic and meroblastic ova at very early stages, the one being that of a rabbit, the other that of a Sauropsidan, and it is to the latter that the ovum of Monotremes bears a close resemblance.

In both cases it is interesting, however, to observe that a structure is eventually formed known in birds and reptiles as the yelk-sac and in most mammals as the umbilical vesicle, the two being really homologous with each other.

Now that Mr. Caldwell has shown that in the lowest mammals a yelk-sac is present containing food-yelk instead of an umbilical vesicle as in the higher forms, it may be affirmed that the curious stages in the development of most Mammalia which result in the pinching off of the embryo and the formation of an umbilical vesicle are indications still remaining of the time when these animals were nourished during early stages, not directly by a close union with the maternal tissues, but by means of yelk-sacs: it affords evidence, in fact, that their ancestors were not viviparous, but oviparous, just as are the lowest mammals now known to us.

During late years various theories have been held concerning the origin of mammals: Balfour formed a hypothetical group—the Pentadactyloidei—in which he supposed the pentadactyle limb characteristic of all the higher vertebrates to have been established: from this he derives two groups—the one including the present existing Amphibia, the other being a hypothetical and somewhat generalised group, from which, though along divergent lines, were developed both Mammalia and Sauropsida. Thus, according to him, the two latter were branches from one common stem, but the Sauropsida could not be considered as the ancestor of the Mammalia.

Other scientific men have held that mammals were derived from Amphibia-like ancestors: with the present Amphibia they were supposed to agree in the presence of a holoblastic ovum, and in the important fact that in both groups two occipital condyles are present, whilst only one is typically found in the Reptilia.

It is interesting to notice that Cope has described, amongst the numerous extinct forms of reptiles which he has brought to light during the past few years, one, called by him the Theromorpha (*Proc. Am. Phil. Soc.*, vol. xix.

[1] See also Owen, "Anat. of Vert.," vol. iii. p. 676; also *Proc. Zool. Soc.*, 1834, p. 143.

p. 38), which he regards as intermediate between Reptilia and Mammalia. He says:—"The order Theromorpha approximates to the Mammalia more closely than any other division of Reptilia. This approximation is seen in the scapular arch and humerus, which nearly resemble those of the Monotremata, especially Echidna; and in the pelvic arch, which Owen has shown in the sub-order Anomodontia to resemble that of the mammals, and, as I have shown, especially that of Echidna. The tarsus is also more mammalian than in any other division of reptiles. In the genus Dimetrodon the coracoid is smaller than the epicoracoid, as in Monotremes. The pubis has the foramen for the internal femoral artery." Cope also appears to have found in the Theromorpha a spur attached to the hind foot, just as in the males of Monotremata.

In the skeletons of the latter, on the other hand, we find several prominent features in which, whilst they differ from the typical mammalian forms, they approximate more or less closely to the reptiles, whilst finally Mr. Caldwell's discovery with regard to the nature of the ovum has shown that Mammalia and Sauropsida are closely allied to each other—more intimately than has generally been allowed by naturalists.

In Monotremes we find, as it were, intermediate animals possessing the attributes of two classes: whilst on the one hand they have developed mammary glands, the distinctive feature of the higher group, on the other they lack that structure whereby the typical mammalian embryo receives nourishment before birth; and in correlation with this we find them agreeing with the lower class in the possession of a yelk-sac, whilst the contained food-yelk causes the ovum to assume the meroblastic type.

We may thus trace the line of descent through the Sauropsida directly to the Monotremes (doubtless through forms now extinct, as the Theromorpha of Cope); from these to Marsupials, which are indeed viviparous, but whose ova still possess a large yelk-sac, and whose embryos, as Mr. Caldwell (*Q.J.M.S.* October 1884) has just shown, enter into no close vascular connection with the maternal tissues; and from these to the higher mammals, whose much specialised structures for fœtal development differ now so widely from those of the lower vertebrates.

W. BALDWIN SPENCER

NOTES

LAST Thursday (December 4) the Chemical and Physical Society of University College, London, gave a scientific *soirée* in connection with the University College Society. Prof. T. G. Bonney delivered the annual address, and took as his subject "Serpentine Rock and its Origin." The lecture was illustrated by Wright and Newton's new oxy-hydrogen microscope. During the evening demonstrations were given on "Radiant Matter" by Mr. Rose Innes, "Absorption Spectra" by Mr. Schunck, and "Ozone" by Mr. E. E. Craves, in various parts of the building. In the library were exhibited by several gentlemen and manufacturers new scientific apparatus and chemical compounds. The physical and chemical laboratories were thrown open to visitors, and in them were shown new forms of apparatus for research. The meeting was numerously attended, and the committee are to be congratulated on the success of the evening.

THE ordinary general meeting of the members of the Parkes Museum was held on Thursday, December 4, Capt. Douglas Galton, C.B., F.R.S., in the chair. The meeting was held to consider the report of the Council for the tenth year and to elect officers. The report set forth the work done in connection with the Museum during the past year, which had included lectures by the Council of the Sanitary Assurance Association in addition to those arranged by the Council of the Museum. The accounts showed that there was urgent need for increased subscriptions if the Museum was to be continued, for the small invested capital had had to be made use of this year to meet the current expenses. The report was adopted on the motion of the Chairman, seconded by Mr. Rogers Field. Mr. Mark H. Judge, then proposed "That the report be printed for circulation, with a detailed statement of the financial position of the Museum, and that a special meeting of the members be convened within two months to consider the same." This was seconded by Mr. E. C. Robins, and carried unanimously. Sir R. Lloyd Lindsay, Prof. J. Marshall, F.R.S., and Mr. Alfred Waterhouse, A.R.A., were elected Vice-Presidents. Six new Members of Council were elected, and the meeting closed with a vote of thanks to the Chairman, proposed by Dr. J. C. Steele of Guy's Hospital.

WE have before us a most satisfactory report of the Manchester Public Free Libraries for 1883–84, showing increase everywhere. More than one and a quarter million of issues have been made to two and a half million of visitors to the libraries. Of these the boys have been provided with additional reading-rooms to themselves, which are reported as crowded every evening; the increased Sunday issues of books also are noted as being specially made to boys, and it cannot be doubted that a taste for reading thus early implanted will save them from half the temptations to which idle youth is subjected. While nearly 10,000 new books have been purchased, more than 10,000 have been started in new harness for fresh toil by the bookbinder; and few items can speak better of "something accomplished, something done," than 3325 volumes withdrawn from circulation, simply worn out. At one branch a new catalogue published, at another one preparing, and at a third two supplementary lists issued, keep the value and the availability of the books at the highest point.

AT the meeting of the Geologists' Association last Friday, Mr. R. Meldola gave a preliminary account of his investigation of the East Anglian earthquake of April 22, 1884, with special reference to the geology of the question. The extreme limits of the recorded disturbance were Brigg in Lincolnshire, Altrincham in Cheshire, Worcester, Bristol, Street (Somersetshire), Boulogne, and Ostend, giving in round numbers an area of 50,000 square miles. The focus of the disturbance appears to have been beneath the earth near the villages of Abberton and Peldon, between Colchester and Mersea Island, and there seems to have been total reflection of the shock at Wivenhoe on the River Colne, the tract of country to the north-east of this village, where great damage was sustained, being in "seismic shadow." The area of structural damage comprised about fifty or sixty square miles, the main axis being along a line five miles in length and extending in a S.W.–N.E. direction from Peldon to Wivenhoe. The evidence showing the propagation of the shock along the older rocks had been carefully considered, and the conclusion had been arrived at that such a spreading of the shock towards the west, north-west, south-west, and south-east had actually taken place, an additional argument in favour of the extension of the Palæozoic rocks beneath the south-east of England, as first suggested by the late Godwin-Austen in 1855, being thus furnished. It was pointed out that this extension of the disturbance along the older rocks was of a purely dynamical character, depending simply upon the superior elasticity of these formations. One phase of earthquake movement which the present disturbance appears to have revealed with special distinctness was the tendency of the shock to make itself felt along free margins such as coast-lines, river-valleys, lines of outcrop, &c. The general conclusion respecting the distribution of earthquakes in this country which the present investigation

had led to was that earthquakes having their focus in the east of England would be likely to extend much further west than those originating in the west would extend eastwards, this depending upon the geological structure of the country and being supported by the records of previous British earthquakes, of which a complete catalogue was in course of preparation. Mr. Meldola stated that the complete report, which was very voluminous, was nearly ready for publication.

WITH reference to the palæontological discovery of a fossil scorpion in the Upper Silurian formation of Gothland, recently made by Prof. G. Lindström of the Academy of Sciences, Stockholm, which has attracted considerable attention on the Continent, we have received the following communication from this *savant*:—"The discovery was made in the latest Upper Silurian layer. Only the thin chitinous coat has been preserved, all the soft membranes having decayed, and the body is compressed, owing to the pressure of the superincumbent layers. Like the scorpions existing at the present time, its body consists of the cephalothorax, seven abdominal membranes, and seven segments in the tail, of which the seventh is distinctly shaped into a poisonous sting. Both the great claws (*palpi*) still remain; the number of legs was eight, those of the left side being in perfect condition. They differ entirely from all known scorpions, fossil or living, by the joints being thick and heavy and the leg ending in a point instead of claws. There is a marked respiratory cavity (*stigma*) on the right side, from which I draw the conclusion that it was not only an air-breathing animal but an animal living on *terra firma*. Its whole construction points to this. It is the oldest known land-animal, the limits of our knowledge as to its existence during past ages having been extended from the Middle Devonian strata of Canada, where remains of Neuroptera have previously been found, to the uppermost strata of the Upper Silurian formations."

THE Mersey Tunnel is now completely arched in under the river with the exception of the inverts. It is interesting to geologists to know that, about three hundred yards from the Liverpool side, the upper part of the tunnel intersected the pre-Glacial bed of the river for a distance of about one hundred yards. This "gully" in the rock was filled with hard Boulder-Clay, with erratic boulders resting upon the hard denuded surface of the Triassic sandstone. As showing the importance of a knowledge of geology in engineering works, this pre-Glacial gully was, in opposition to the prevailing opinion, foreseen and predicted as one of the difficulties that would have to be encountered in the tunnel-works in a paper by Mr. Mellard Reade, entitled "The Buried Valley of the Mersey," published in the *Proceedings* of the Liverpool Geological Society in 1872. It is very satisfactory to know that this difficulty is now surmounted, and the stability of this important and interesting work placed beyond a doubt.

As we anticipated some weeks ago, M. Joseph Bertrand has been elected a Member of the Académie Française almost without opposition, having obtained twenty-five votes out of a total of twenty-six, the single dissentient voice having been given in favour of a poet who could hardly be termed a candidate. M. Bertrand's formal reception into the Academy will take place in the course of a few months, and M. Pasteur is to reply to the speech he will deliver on the occasion.

M. JANSSEN is at present engaged in drawing up for the Academy of Sciences a full report of his mission to the Prime Meridian Congress at Washington. He is also to deliver a lecture on the subject before the Geographical Society of Paris. The learned astronomer still adheres to his scheme of a neutral meridian.

MANY of our readers are aware that when Mr. Thiselton Dyer, more than ten years ago, introduced at South Kensington a system of instruction in botany based on the same principle as the instruction in animal morphology already introduced by Prof. Huxley, he intended to put together the results of his experience in the form of a hand-book for the use of other teachers. Pressure of other work prevented his carrying out his intention, but Mr. F. O. Bower, now Lecturer in Botany in the Normal School of Science, took the task in hand in conjunction with Dr. Sydney Vines, and we are glad to be able to announce that Messrs. Macmillan and Co. will publish a first instalment of the work immediately. When complete, according to the original scheme, the work is intended to contain a general introduction by Mr. Dyer, introductory chapters on methods and on the morphology of the cell by Dr. Vines, and then the description of a series of types representing the various groups of the vegetable kingdom. In each case a short general description will precede the directions for investigating the type in the laboratory. The instalment now promised will contain an explanatory preface by Mr. Dyer, the two introductory chapters by Dr. Vines, and the directions for laboratory work on vascular plants, as represented chiefly by the following types:—*Helianthus annuus*, *Ulmus campestris*, *Zea Mais*, *Pinus sylvestris*, *Selaginella Martensii*, *Lycopodium clavatum*, *Aspidium Filix-mas*, and *Equisetum arvense*. It is hoped to publish the laboratory directions for the remaining types, and the short prefaces to each type, before very long. For the laboratory directions Mr. Bower is mainly responsible; the descriptive prefaces will be contributed by Mr. Dyer; but the whole work will have undergone the minute supervision of all the three authors concerned, and represent their united experience.

MESSRS. MACMILLAN AND CO. promise immediately an abridged edition, for popular use, of the "Life of Prof. J. Clerk Maxwell."

THE following are the lecture arrangements at the Royal Institution before Easter 1885:—Six lectures (adapted to a juvenile auditory) by Prof. Tyndall, on the Sources of Electricity, on December 27 and 30, 1884, January 1, 3, 6, and 8, 1885; five lectures by Prof. H. N. Moseley, on Colonial Animals, their Structure and Life-Histories, on Tuesdays, January 13 to February 10; four lectures by Dr. Arthur Gamgee, on Digestion, on Tuesdays, March 3 to 24; eleven lectures by Prof. Dewar, on the New Chemistry, on Thursdays, January 15 to March 26; three lectures by Dr. Waldstein, on Greek Sculpture from Pheidias to the Roman era, on Saturdays, January 17 to 31; three lectures by Mr. G. Johnstone Stoney, on the Scale on which Nature works, and the Character of some of her Operations, on Saturdays, February 7 to 21; and five lectures by Mr. Carl Armbruster, on the Life, Theory, and Works of Richard Wagner (with illustrations, vocal and instrumental), on Saturdays, February 28 to March 28. The Friday evening meetings will begin on January 16, when Prof. Tyndall will give a discourse on Living Contagia.

THE archæologist M. Saillard, well known through his indefatigable efforts for the preservation of dolmens, has discovered the workshop of a prehistoric armourer or smith on a steep rock by the sea on the south-west side of the peninsula of Quibéron (Brittany). It dates from the Stone Age. Polished lances, arrow-heads, axes, and other objects are represented in great numbers and in every stage of manufacture, so that the discovery is most interesting, inasmuch as the objects illustrate the workman's method and process. Amongst the objects is also a meteoric stone worked into an implement. The skeleton of the workman was also found, the skull being very well preserved.

DR. AUGUSTUS VOELCKER, F.R.S., died on Friday last, the 5th inst., at his residence, 39, Argyll Road, Kensington, in his sixty-second year. He was born at Frankfort-on-the-Maine,

received his chief education at the University of Göttingen, and in early life came to England. After that time he successively held the post of assistant to the late Prof. Johnston at Edinburgh, Professor of Chemistry in the Royal Agricultural College at Cirencester, and Professor of Chemistry to the Royal Agricultural Society of England, and was well known as the author of several works in theoretical and agricultural chemistry, such as the "Chemistry of Food" and the "Chemistry of Manure."

THE *Journal of Botany* for December contains a memoir of the late George Bentham, accompanied by an excellent photograph.

WE have received the prospectus of the Royal Agricultural College, Cirencester, issued during the past month. The course of instruction provided in technical and scientific subjects appears to be ample for the requirements of the agricultural students. We are glad to notice that external examiners are appointed for the final examination of students for the diploma, and also that a Board of Studies, in which are several professors otherwise unconnected with the College, exists. The number of students is steadily increasing, and among them are several Indian scholars sent by the Governments of Bengal and the North-West Provinces. The Governments of the Indian Presidencies also encourage some of their civil servants to pass through the College course when on leave of absence in this country.

ON the subject of agricultural education, a correspondent writes to the *Times* that a number of meetings have recently been held in Oxfordshire and Buckinghamshire with a view to the establishment of night classes during the winter for teaching the scientific principles of agriculture. There is, he says, a growing opinion among the more educated young men that agriculture requires something besides Commissions and inquiries and fair trade. It has been estimated that the annual waste from careless and unskilful methods of managing manure amounts to nearly five millions sterling. Add to this the want of knowledge in the purchase of artificial manures and their application, the waste of feeding-stuffs, the odd pieces and corners of fields that might grow other things beside rank weeds and couch-grass, and the waste of time in going to markets, auctions, and fairs. No reduction of rent or local taxation, or increased price of wheat, will, says this correspondent, do anything for men who make no effort to improve their industry by increased scientific knowledge. The natural history of the wire-worm, the leather-jacket, the dissolving of bones, the building up of plants, the judicious mixing of food, and many other things which farmers would be the better for knowing can never be acquired by what is called practical farming, and accordingly these classes are commended to the consideration of all who take an interest in the welfare and education of young men in rural districts.

THE additions to the Zoological Society's Gardens during the past week include a Yellow Baboon (*Cynocephalus babouin* ♂), a Chacma Baboon (*Cynocephalus porcarius* ♀) from the East Coast of Africa, presented by Capt. Edward Jones, R.N.R.; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. Geo. Airey; a Bittern (*Botaurus stellaris*), British, presented by Mr. Robert Page; a —— Otter (*Lutra* ——) from South America, a Cat Fish (*Amiurus catus*) from North America, deposited; two Rock Pipits (*Anthus obscurus*), British), a Passerine Owl (*Glaucidium passerinum*), a Crested Titmouse (*Parus cristatus*) from Siberia, purchased.

OUR ASTRONOMICAL COLUMN

WOLF'S COMET.—Herr Lehmann-Filhés of Berlin has made a first approximation to the amount of perturbation experienced by this comet at its near approach to the planet Jupiter in 1875, to which attention was directed in NATURE (vol. xxx. p. 615). He adopts the orbit determined by Prof. Krueger upon observations extending over an interval of forty-eight days, and applies the formulæ of the "Mécanique Céleste" (liv. ix. chap. ii.), which were first employed by Burckhardt in the case of the celebrated Lexell comet of 1770. The following are the elements deduced for perihelion passage in 1868, or the elements defining the orbit of the comet previous to its close approach to Jupiter; we annex Prof. Krueger's orbit for the present appearance for comparison:—

	Lehmann-Filhés, 1868	Krueger, 1884
Perihelion passage ...	Sept. 24·6 M.T. Berlin ...	Nov. 17·7922
	° ′ ″	° ′ ″
Perihelion	352 36 48	19 3 17
Ascending node	207 33 50	206 22 17
Inclination	27 36 49	25 15 10
Angle of excentricity ...	16 11 5	34 3 12
Log. semi-axis major ...	0·663970	0·552936
Mean daily motion ...	358″·14	525″·536

The longitudes in both orbits are reckoned from the mean equinox 1884·0.

Prof. Krueger writes modestly as to the degree of accuracy of his elements, which have been adopted by Herr Lehmann-Filhés, nevertheless they were founded upon a fairly-wide interval of observation as noted above. From the nature of the problem, however, the orbit for 1868 must be regarded as roughly indicating the kind of track which the comet was then following. And it is to be remarked that the perihelion distance corresponding to the assigned values of excentricity and semi-axis major is 3·327, which would account for such a comet not having been observed while moving in the orbit of 1868. Thus, as in several previous cases, the comet appears to have been brought within range of visibility from the earth by the powerful attraction of the planet Jupiter.

THE WASHBURN OBSERVATORY, WISCONSIN.—Vol. ii. of *Publications* of this Observatory has been issued. Its main feature consists in a reduction of the star-gauges of Sir William Herschel, published and unpublished, or 683 gauges published and 405 unpublished, Prof. Holden having been indebted for the latter to Lieut.-Col. Herschel, R.E., who forwarded to him a complete copy of a manuscript, by Miss Caroline Herschel, in which they are given, and who was at the further trouble of extracting from the Herschel papers in the library of the Royal Astronomical Society the dates of the various sweeps. Also of 500 counts of stars from the published charts of Prof. C. H. F. Peters, 983 counts from his unpublished charts and those of Watson and Chacornac, and 781 from those of Palisa. Prof. Holden states that he is now discussing these various gauges by a graphical process, and that they promise to lead to very interesting results, especially when they are supplemented by other star-gauges covering the same ground and made by a larger instrument. The volume further contains a list of 111 new double-stars and two new nebulæ, with observations of red or coloured stars between December 1881 and the end of 1883, in continuation of a list given in the first volume.

GEOGRAPHICAL NOTES

REPORTS have been received from M. Alfred Marche, who is travelling through the Philippine Archipelago on a scientific mission for the French Ministry of Public Instruction. During June and July last he explored the archipelago of Calamienes, situated to the south-west of Mindoro and to the north of Paluan (Paragua) Island. This archipelago is composed of three large islands, Busuanga, Calamienes or Culion, and Linacapan, and about thirty smaller ones. M. Marche first visited Culion, the inhabitants of which are Tagbannas, similar to those whom he observed in a previous journey to Paluan. These form the principal as well as the most ancient people of the peninsula, and it is probable that formerly they occupied a much larger area than they do now. A small number of them, more or less Christianised, have submitted and built a village, to which, however, they come as rarely as possible. The others are independent, and are fetish-worshippers. In Culion there is but a single Spaniard, the priest. After Culion, M. Marche visited the island of Busuanga, where there were formerly Chinese colonies engaged in collecting birds' nests, and in trepang and pearl-fishing, both industries which no longer exist. In spite of continual rains the traveller was able to make a large collection of plants and of woods of all kinds. In Busuanga he came

across the inhabitants of Agutayo, one of the Cuyos Islands. They left their home, where they could hardly get enough to bring them to Busuanga, to fish for trepang and for small prawns, which they dried in the sun, and then sold to Chinese and Indians. M. Marche was able to take measurements of a certain number of these Agutaino. He gives long and interesting ethnographical details of the Tagbannas of this island, on their marriage ceremonies, funeral rites, &c. M. Marche then went in succession to the islands of Penon, Coron, Magao-Puyao, and Dibatac. In the last he observed that the hills, which are almost disafforested by the natives, and which are about two hundred metres in height, surround fertile plains in the form of a horse-shoe, more or less closed, and in the centre a depression is observable. The whole has the appearance of a funnel, and it is suggested that this is an extinct volcanic region. In the same island of Dibatac, crocodiles and boa-constrictors are very numerous, and M. Marche was able to capture one of the latter, which had swallowed a calf several months old.

On the 2nd inst. Mr. H. M. Stanley inaugurated the newly-formed Scottish Geographical Association in the Music Hall, Edinburgh. Lord Balfour of Burleigh presided. On the 4th Mr. Stanley formally opened the rooms of the Society, and on Saturday last he opened the Dundee branch of the Scottish Geographical Society in the Kinnaird Hall.

M. Romanet de Caillaud has communicated to the Geographical Society of Paris two papers on Tonquin. One refers to routes from the delta of the Red River into Yunnan, the other on the history of the Thai or Laos race in Tonquin and Southern Kwangsi. In the former he describes in detail five routes, two by river and three by land, into South-Western China. The only one of these of importance is that by the Songkoi, or Red River, and M. de Caillaud makes light of its difficulties, and insists that Paris is practically nearer to the Yunnan frontier than either Canton or Pekin. Paris is at the most, he says, fifty days' journey, while Canton is sixty, and Hankow, on the Yang-tse, eighty days. He also advocates this route for an invasion of China, and says that Lao-kai, on the upper Songkoi, is really for France the vulnerable point of that Empire. As has been already pointed out, discussion of the Songkoi route above Hong-hoa must for the most part be based on speculation, as only one European has travelled down or up the river from or to Manhao, and his journey was undertaken in circumstances which hardly admitted of accurate observation. A German geographer has recently expressed the opinion that one of the chief difficulties to be encountered in this route will be ethnological, and M. de Caillaud, in his second paper, traces briefly the fortunes of the principal race of the region—the Laos or Thai. This people has apparently had its day. At one time it dominated the whole Indo-Chinese peninsula, but now it is split up among a number of independent or semi-independent princelets, whose main business is war and piracy. Their various attempts to recover a portion of their old power have been repressed by the Annamites, assisted, when necessary, by the Chinese.

Lieut. Bove, of the Italian Navy, has written to Dr. Hyades of Paris a letter respecting his second expedition to Terra del Fuego The first, he says, was to some extent scientific. He was ordered by the Argentine Government to study the south of Patagonia and Terra del Fuego from an economical point of view, and scientific observations were merely adjuncts. Nevertheless a scientific commission to investigate the geology, botany, zoology, and hydrography of these regions was sent with him. Lieut. Bove's official report is about to appear in Spanish in Buenos Ayres, and will be accompanied by those of the scientific men engaged. The *Bolletino* of the Italian Geographical Society will contain a paper on his journey in the interior of Terra del Fuego among the Ona. He started from Ouchonaya with an escort of twenty-four Fuegians of the mission, who proved very useful to him. After crossing the mountains behind this place, he descended into the valley which runs down to Admiralty Sound. He describes the interior of the island as magnificent, and much richer than Patagonia. The Ona were met with but twice, and their total number is estimated at from 300 to 400. The total number of Fuegians in the whole archipelago is stated, according to a careful census made by an English missionary, the Rev. Thomas Bridges, to be only 949 men, women, and children.

M. Michel Venukoff has addressed a note to the Geographical Society of Paris, referring to a new map of the island of Saghalin, prepared by M. Nikitine, the topographer. It differs from all the other maps of the island in some respects. It shows it to be considerably larger than had been previously believed. M. Reclus gives the area as 63,600 square kilometres. M. Strelbitsky 67,018, and Venukoff 73,529. Although the writer claims that his bases for calculation were necessarily more detailed and exact than those of his predecessors, he nevertheless considers his figures as approximate rather than final.

SCIENTIFIC ASPECTS AND ISSUES OF THE INTERNATIONAL HEALTH EXHIBITION[1]

[THE first Wednesday lecture at the Society of Arts was devoted to an address on this subject—in accordance with precedents—the Duke of Buckingham, Chairman of the Exhibition Council, taking the chair. The following are the parts of the address relating to the scientific departments of the Exhibition, and the proposal which the lecturer is understood to have laid before the Council for some time for the disposal of the surplus to such objects.]

There was only one exhibit in the food department to which I would specially call attention, it was that from the collections of the Science and Art Department and the Parkes Museum, illustrating the constituents of food and food values, and the connected exhibit by the Society of Public Analysts, of materials used as adulterants of articles of food; of adulterated articles of food commonly sold in this country; of adulterations which have been suppressed; of adulterations practised abroad, and mixtures generally protected by labelling. This latter was added in consequence of a suggestion made by the late Mr. Wigner, President of the Society of Analysts, at a late date in the progress of the Exhibition. I am afraid that it did not attract all the attention that it deserved. I trust, however, we shall be able to reserve it for continual public reference. Mr. Wigner, in communicating with me, pointed out that, although the Exhibition was most successfully arranged so as to display in a prominent manner all the articles connected with food, yet the public were only shown what is done by the most careful and respectable firms, whose names are a sufficient guarantee that only materials of the highest quality are used in the preparation of the goods which they show.

All who are connected with food produce know how, from time to time, the desire on the part of the consumer for cheap goods is the cause of the introduction of articles called "substitutes," which are offered to the manufacturer at one-third the price of the genuine material, and which frequently consist of some cheap and simple preparation, the very opposite in its chemical character to the article for which it is said to be an efficient substitute: several cases of this kind had recently been brought to Mr. Wigner's notice. For instance, he referred to an article to be used as a substitute for tartaric acid, the composition of which has been found to be acid sulphate of alumina in solution—a substance which, if introduced into the manufacture of bread or biscuits, is as objectionable as alum, and quite as much an adulterant. Bisulphate of potash is also sold under a name similar to tartaric acid, and is equally as worthless as sulphate of alumina. These are only two instances out of many, and serve as an additional argument to show the keen competition in trade, which causes the manufacturer to produce, and unscrupulous firms to sell, such articles under "Royal Letters Patent," or some other heading of this sort, to attract the notice of the consumer.

The public analyst, Mr. Wigner added, although, of course, he should be cognisant of these facts, has quite enough work for the remuneration paid to him, and in addition to this, there is the fact that the Sale of Foods and Drugs Act is so limited in its aim and scope as to practically prevent the analyst from testing anything but the common articles of food, such as bread and milk, unless they are sold under some recognised name. Let him once travel outside these lines, and a whole host of objections are raised. What is really wanted is more stringent legislation, similar in character to that at present in operation in the United States and Paris.

In the French Section were shown the monthly reports of the Municipal Laboratory, showing the complete and thorough manner in which the food-supply of that city is protected. Why cannot something of the same sort be done in London? What is wanted is a measure defining what is and what is not adulteration, and prohibiting the use of articles which are fre-

[1] Extracts from an Address delivered at the Society of Arts on Wednesday, November 26, by Mr. Ernest Hart, Member of the Executive Council.

quently employed at the present time, and the sale of which, while benefiting one class, seriously injures another, by substituting an inferior article for one of better quality.

Considerable good, it may be hoped, was done by the Health Exhibition by the exhibition of these so-called substitutes. The prominent display of this instructural series in a National Exhibition has, we trust, done something towards putting a stop to a trade which, while it enriches the unscrupulous trader, places the honest manufacturer in an awkward position.

How far it has fulfilled this intention is of course not yet apparent, but I shall certainly feel it a part of my duty in another capacity, as Chairman of the Parliamentary Bills Committee of the British Medical Association, to endeavour to keep the attention of our legislators to this important subject. It may be hoped that, when the political horizon is sufficiently cleared to enable Parliament to devote some time to interests of almost as important, if less strictly party, a character as those which are now occupying their attention, that it may be possible to secure for the people of England, or at least for the people of this metropolis as an example to other great towns, some of those better securities against the adulteration of food which this country was the first to set the example of creating by legislative action, but as to which it has at the present moment fallen behind some of those countries which followed us, such as France, Belgium, and America. It is within my knowledge, and in fact within my personal experience, that in all those countries our English legislation was originally the model which they set before them. In fact, in the case of several of these countries, I have had the opportunity of receiving the gentlemen who had been sent over by their various Governments, and of furnishing them in several instances with the opportunities of study and materials of which the respective Governments have availed themselves to create model laws respecting adulteration; I would refer here especially to the German code.

It is hardly to our credit that we have allowed ourselves to be distanced in a race in which we had so considerable a start, and in which the sole goal is the public benefit, and the maintenance of the public health. These are questions largely affecting the health of the whole nation, and especially affecting the welfare of the poor, who suffer most by the substitution of worthless, inferior, or adulterated articles in the fabrication of apparently cheap, but often very dear because worthless, articles of food.

Heating, Ventilation, and Smoke Abatement.—The testing of exhibits in Classes 24 and 25—Heating and Ventilating—were carried out on a considerable scale. Some 120 kitcheners—some burning solid fuel, and some gas—were tested. A large house was rented for conducting these trials, under conditions approximating to those which would be found in the actual use of the apparatus by the public, and a large number of tests of cooking joints, &c., in the kitcheners, &c., were made. The importance and necessity of exact testing, initiated by the Smoke Abatement Committee of 1881, and since carried on in a systematic manner by the National Smoke Abatement Institution, were fully recognised by the Executive Council of the Health Exhibition. The series of testings were conducted by the acting engineer to the Smoke Abatement Institution, Mr. D. K. Clark, and the jury of the Exhibition dealing with these exhibits included Prof. W. Chandler Roberts, Mr. Robert Harris, President of the Gas Institute, and other members of the Smoke Abatement Institution whose special knowledge peculiarly fitted them for the work.

The practical advantages of such testings have been manifested in the great interest taken by exhibitors in the work, their general desire to submit their manufactures for testing, the evidently accelerated course of improvement in design since the Smoke Abatement Committee first introduced the system of tests, and the advanced knowledge derived from the results of those tests.

At the Health Exhibition these beneficial influences were clearly traceable in the adoption of good ideas embodied in apparatus shown at the Smoke Abatement Exhibition in 1881, and brought into notice by the testing treatments adopted there, as well as in the rejection of plausible but impracticable methods of heating and ventilation which found place in the earlier exhibition. The detailed report of the tests of the apparatus shown at the Health Exhibition I trust will be published, for it will form a valuable addition to a continuous and advancing series of tests. The importance of this branch of my subject can hardly be exaggerated. We can follow, in the light of the knowledge derived from the result of the later tests, a regular and most encouraging course of improvements. For example, some of the exhibits shown at the Crystal Palace Exhibition last year, in the class of gas-cooking and heating-stoves, were proved to have a greater efficiency, by about 20 per cent., than those shown at the Smoke Abatement Exhibition in 1881; while at the Health Exhibition the efficiency proved by the tests was fully 25 per cent. greater than at the original Smoke Abatement Exhibition. Besides this increased efficiency, or improvement, to be measured by lower consumption of gas for equal work done, there has been an improvement hardly less important in numerous points of detail, affecting both the durability of the apparatus, and the facility with which it can be cleaned. These latter improvements, added to the lessened price of gas, and the reduced consumption of it in the newer forms of stove, cannot fail to tend towards the increased use of these cleanly conveniences and smokeless heating appliances for domestic purposes.

The testings at the Health Exhibition brought out the merits of a number of kitcheners and stoves very well adapted for using coke and "slack," or small coal, as well as improved patterns for using the ordinary lump coal, with lessened production of smoke. In regard to the advance made in smoke prevention from domestic fires, I may mention, on the authority of the testing engineer, that the highest average smoke shade proved by the tests of 1882 was 4·18 from kitcheners; and in the test at the Health Exhibition, the highest average was only 2·4; and from open grates the average density of the smoke was 3·0 in 1882, and at the Health Exhibition it was only 1·75. The importance of facilitating, by means of improved apparatus, the use of coke and the cheaper fuels now generally wasted is obvious, and I think I may fairly claim that this section of the Exhibition achieved a highly useful and successful result. In the bakeries department no less than five distinct systems of heating bakers' ovens, practically without the production of any smoke whatever, were shown—and not only shown, but were proved by an extended course of actual working—to be more or less well suited to the requirements of the trade. Varieties of machines for making dough by cleanly and expeditious methods were successfully worked throughout the period of the Exhibition, and it is but reasonable to assume that the exhibition of these machines, shown daily in satisfactory working, must have a great future influence in putting a stop to the laborious and filthy process of making dough by manual labour.

The Library.—The library sub-committee report with great satisfaction that the library has proved an unqualified success, and that it has attracted not only a large number of readers, but a considerable proportion of serious students.

Although no purchases of books have been made, upwards of 5000 works are now included in the collection, of which over 3000 relate to health subjects. The great majority are free gifts, a small proportion are on loan. They express a strong hope that a collection of books so useful as the nucleus for the formation of a special library will not be dispersed, but that the Executive Council will devise means to maintain the library on a permanent footing, as part of a memorial of this useful and successful national undertaking.

The library was altogether a novel feature in any exhibition of the kind, and its value was attested by the considerable number of serious students who availed themselves of its extensive resources, many of them being University students, who used this unwonted opportunity in preparing for examinations. The advantages to be derived from retaining the library as a permanent institution would be great. I put before you a copy of the catalogue, made entirely by Mr. Carl Thimm. This catalogue is in itself a publication of no small interest, being the most complete catalogue of sanitary literature with which I am acquainted (although of course it cannot be said to be complete in even an approximate sense, but must only be regarded as a very valuable nucleus for a larger library), in which the hygienic literature of foreign nations, and especially their official hygienic literature, is very largely and well represented.

The Sanitary and Insanitary Houses.—Of the sanitary and insanitary houses a special handbook has been published, which will be preserved among the literature of the Exhibition, and which constitutes a small epitome of the ordinary defects of existing houses, and the simple means by which such defects may in future be avoided. I shall not enter into any description of these houses, for they are already well known to most of you, and may, I yet hope, be further studied on some future occasion. But I wish to draw your attention to the very important conferences on the sanitary arrangement of houses which were held

by the Institute of British Architects in connection with this part of the Exhibition, and especially to that held in the last days of the Exhibition by the Guild of Plumbers. This I call your attention to because there is good reason to hope that out of this will spring an organisation, and I trust a legislation, which will, perhaps, do more towards the preservation of health and the saving of life than most of the much more pretentious forms of legislation which we must contemplate in the near future. The Exhibition will, in virtue of the organisation likely to follow from this conference, become the means of drawing together all those scattered forces which have for some time tended in the direction of a great improved regulation of the sanitary condition of our houses: a force, however, which, up to that moment, there seemed but little hope of being able so early and so practically to organise. I feel a peculiar interest in this subject, for I have now for several years, as Chairman of the National Health Society, and in connection with the Sanitary Section of the British Medical Association, occupied myself with collecting the facts and figures which demonstrate the urgent necessity of improved legislation for the safeguarding of the sanitary construction of our houses, and the improved education and registration of those builders and plumbers to whom we intrust that construction. I read on this occasion at the opening of the Congress a paper which I had prepared three years before, and which, in fact, I have in various forms presented to several professional and lay bodies, with the view of forming and gauging public opinion on the subject. I shall venture to put before you here now only the conclusions which I laid before this Conference, which practically and in principle received their approval, and which will thus, I hope, have an earlier chance of finding their way into the statute-book. They have the object of strengthening our statute law as to drainage and plumbing. I desire to enlist the aid of the Society of Arts in bringing into legal operation, as one result of the International Exhibition, the proposals which will be found in the Report of the Conference, of substituting sanitary for insanitary houses.

First as regards drainage itself:—

(1) Rural authorities should have the same powers as are now possessed by urban authorities. In the suburbs of towns, just outside the municipal boundaries, thousands of houses are springing up without any sanitary supervision whatever. The rural authority is, perhaps, unaware of the evil, or is, at any rate, careless about it until the houses are erected; and their opportunity of making by-laws which can control such houses is then lost.

(2) It would be well that the requirements of the Model By-Laws as to New Buildings issued by the Local Government Board should be incorporated in a Building Act which should be forthwith passed, and be of general application throughout the country.

(3) The plumbing and drainage of all buildings, public and private, should be executed in accordance with plans and specifications previously approved in writing by the local authority.

(4) No drainage-work should be allowed to be covered or concealed in any way, until it had been examined and passed by the surveyor.

(4A) The efficiency of all drains should be tested by the peppermint or some other test before they are passed; and it should be a rule that, wherever possible, drain-pipes should be kept from view only by boarding which can be readily removed.

(5) No new house should be allowed to be inhabited until it had been passed and certified by the surveyor, and a plan of the system of drainage should be appended in every case to the lease or other document for the letting of the house.

As regards the plumbers, I suggest that—

(6) The names and addresses of all plumbers should be registered by the local authority, and no plumber should be able to carry on his trade until he had been so registered, and had received a license from the local authority.

(7) Before the license is granted to him the plumber should attend personally at the office of the local authority, for examination as to his qualification as a plumber.

(8) Such licenses should be renewed from year to year, and their continuance should depend upon the good behaviour of, and the return of the work done by, the licensee.

(9) The names of all licensed plumbers should be publicly advertised once a year by the local authority.

The result of this Conference will live. Before long, I think we may promise ourselves, we shall see, as one result of this Exhibition, an active movement set on foot by which we shall henceforth be enabled to train skilled and educated workmen, and to ascertain by suitable tests their efficiency, and by which we shall be enabled to protect our artisans and ourselves from occupying houses which have been built with a total disregard or flagrant defiance of the first principles of sanitary construction, and of the conditions which we all know to be primarily essential to healthy occupation.

The Health Laboratories.—I pass to the laboratories. It did not at first, I think, appear evident to some of the members of our Council how close was the connection between the work to be carried on in these laboratories and the public health. Happily, however, that feeling soon gave way to one of acquiescence in the proposition which I made for the establishment of these laboratories, and, since, a closer examination of the subject has, I think, convinced every one that it is to establishments of research and of study, such as those over which Mr. Watson Cheyne and Prof. Corfield presided, that we must look for the most solid foundations for future progress in solving the highest problems connected with the preservation of health; and that no part of the Exhibition fulfilled a higher purpose, and to none can we look with more assured hope in the future, than to these departments of the Exhibition. A description of the laboratories appears in the official catalogue, and I shall not occupy your time with any description of them.

At the Hygienic Laboratory, in its chemical and physical departments, the public were not merely given the opportunity of seeing hygienic analyses of various kinds going on, and of having them explained to them either by Prof. Corfield or his assistants, individually or in the form of popular demonstrations—of which a considerable number were given, chiefly by the senior assistant, Mr. C. E. Cassall, during the time the Exhibition was open—but they also had the opportunity of seeing the ordinary working of such a laboratory, from the fact that Prof. Corfield was able to utilise this laboratory for his students. A class of about forty teachers, seleeted by the Science and Art Department from schools in all parts of the country, attended a course of lectures given by him at the Normal School of Science, and at the same time worked in batches in the hygienic laboratory at the Health Exhibition, and thus the public were enabled to form an idea of what such a laboratory is in full working order; and, indeed, during the whole time that the Exhibition was open after the above-mentioned class had dispersed, there were pupils who worked in the laboratory.

In a complete hygienic laboratory there should be a separate part set aside for physical experiments relating to hygienic appliances; but in this laboratory there was barely space for the chemical work to be carried on, and even the microscopical work could only be prosecuted to a limited extent, insomuch that the class of teachers went through their course of microscopy relating to hygiene in the physical laboratory at the Normal School, and the absence of physical appliances was replaced, as far as it could be, by demonstrations given by Prof. Corfield at the sanitary and insanitary houses.

As regards the Biological Laboratory, it is sufficient for my purpose to-night to remind you that in it Mr. Cheyne, the worthy pupil of Sir Joseph Lister, who acted as chairman of the Laboratory Sub-Committee, showed by practical working, and by collections such as had never before been seen in this country with the same completeness, the refined methods of research and of teaching by which we are enabled to study the life-history and the habits, the development and the means of arresting the development, of those minute organisms which modern science has shown to be prime factors in the causation of a great proportion of the most fatal diseases which afflict our flocks and herds, which decimate mankind, and which attack those plants and animals which constitute the staple of our food-supplies. Mr. Cheyne's demonstrations were eagerly followed by health students from all parts of the kingdom. A certain number of tables were set apart for study and research, and these were fully occupied from the first to the last days that the Exhibition was open. In Dr. Corfield's laboratory was collected the apparatus for that kind of instruction in the chemical and physical examination of soil, air, water, food, clothing, and materials of house construction, which are essential elements in the education of that great army of medical officers of health who are appointed now under existing Acts of Parliament to watch over the health interests of the community. It is very well known, however, that a large majority of those gentlemen have not this necessary instruction, and that at the present moment there does not exist in this country any adequate means for giving such instruction. There are in England 1102 medical

officers of health, and 996 inspectors of nuisances, all of whom are expected to get their information and to acquire the technical knowledge of which they stand daily in need as best they can; and it is well known that a large proportion of them are very imperfectly equipped with the necessary knowledge, and indeed can hardly be said to possess even the rudiments of systematic technical education in subjects in which they are presumed to be experts, and which they are called upon to decide in matters largely affecting the pockets of the community and intimately concerning its health. In order to illustrate the importance of the establishment in this country on a permanent footing of such laboratories as those which were shown in temporary working at the Exhibition, I shall ask leave now to refer you to an exhibit which was made in the French Court, illustrating the work done by M. Pasteur in a similar laboratory to that of which I am now advocating the permanent establishment, as the best possible sequel of this great Exhibition.

M. Pasteur is the scientific director of the École Normale supérieure in Paris, a school especially designed to supply professors in literature and science to the *lycées* or higher schools of France. He is not, however, called upon to undertake teaching, but is expected to devote all his time to his researches. In a word, in consideration of the considerable national services which he has rendered, an exceptional position has been accorded to him. He receives a professorial salary of 400*l*. a year. M. Pasteur is also the head of l'École des Hautes Études, of which Mr. Chamberlain is the sub-director. In this laboratory he receives some pupils. He possesses further a laboratory at the École Normale, where M. Roux is his coadjutor, and where are admitted some students who are generally persons already known for their studies. He has entire freedom of the choice of students of the laboratory of l'École des Hautes Études, as well as those of persons who work in his private laboratory at the École Normale. About 800*l*. a year are allowed for this laboratory by the Minister of Public Instruction, and for the last few years, 30,000 francs from the Minister of Commerce and Agriculture. These grants are renewed yearly.

The principal researches of M. Pasteur have related to—

(1) *Wine*, in which he demonstrated that, in order to avoid the transformation of alcohol into acid, it is necessary to destroy the germs remaining in wines which are poor in alcohol, by heating them up to 55°-60° Centigrade. He has also studied the action of oxygen and light on wine, and has demonstrated that it is to this action, *i.e.* to the oxidation of the materials of wine, that we are to attribute the development of the bouquet of wine, *i.e.* the flavour which it acquires with age. In order that this may yield a product appreciated by amateurs, it is necessary that it should proceed slowly. He has further demonstrated that the ferment of wine exists on the surface of the grape when it has ripened. He has demonstrated the useful and precise indications which the areometer furnishes, in order to appreciate during fermentation the state of the *mout* of the grape.

(2) *Beer*.—After having demonstrated that brewers employ, generally, a ferment containing, among others, injurious germs, M. Pasteur indicates the following means for obtaining a pure ferment. A small quantity of pure yeast is prepared according to the exact rules of the laboratory. This is introduced into a large copper pan, three-quarters filled with the wort of beer, which has been first carried to the boiling-point, and then cooled before the introduction of the yeast. The vessel only communicates with the external air by a long tube of copper, many times bent, in such a way as to permit the gases to escape without external germs being able to enter. When the wort has been developed, it is drawn off by a tap placed in the lower part of the apparatus, and which is previously purified with the flame of a spirit lamp. The wort of the beer is put to ferment in a large white-metal vat, resting on a plank, and closed by a movable cover, this movable lid dropping into a groove which is kept full of water. As the wort arrives in a boiling state in this vessel, it destroys any germs which may exist there. When it is cooled, and the cooling may be rapidly aided by the use of external cooling water, the yeast is introduced through an opening in the lid. The aëration of the fluid is obtained by two tubes curved downwards, by one of which carbonic acid escapes, and by the other the air enters after being previously filtered through a layer of cotton wool rolled round a cylindrical cage on metal wires which cap the extremity by which the air enters. This apparatus, like the foregoing one, reproduces exactly the conditions which are found to be necessary in the laboratory to prevent the introduction of external germs. The aëration by these two tubes is sufficient, for the carbonic oxide being heavier than air, they are placed in such a way as to form a siphon; moreover, during the fermentation, the wort is certainly kept in movement by the ebullition of the gas which escapes, so that the aëration, although less active than in some of the technical apparatus previously in use by brewers, is more than sufficient. By employing this procedure, secondary fermentations are no longer to be feared, and the spoiling of beer by secondary fermentation is almost entirely put an end to.

(3) A third and profoundly interesting series of researches, which have had a great influence on agriculture, carried on by M. Pasteur, are those relating to *charbon*—the malignant pustule or black quarter of cattle and sheep. M. Pasteur has demonstrated that animals of the ovine and bovine species may be prevented from contracting the disease of *charbon* by inoculating them with attenuated germs, obtained by artificial cultivation of the specific minute organism which is ascertained to exist in the case of *charbon*, and to be the efficient cause of the disease. This attenuated preventive material for inoculation is obtained by the aid of what are known as cultivations of the germs made in special liquids. After the first inoculation with the highly attenuated virus, Pasteur has shown that the second inoculation may be made with a product of medium virulence, and that the animals thus twice vaccinated were unsusceptible of contracting the disease. Pasteur has further demonstrated that the bacterium of *charbon* is capable of retaining its vitality for several years in the earth, and that, when brought to the surface by earth-worms, it is capable of infecting the animals which eat the grass polluted by its contact, especially if the grasses or plants so eaten be hard, and such as to cause abrasions in the mouth and digestive tube.

(4) *Silkworm Disease*.—M. Pasteur, after having assured himself that normally, and in good health, silkworms never contain, at any moment of their life, the bacteria or corpuscles seen for the first time by Guérin Menneville, demonstrated that the eggs of the worms, even when only slightly attacked, contained a great number of these corpuscles or bacteria, which developed in considerable quantities when the animal underwent its metamorphoses, and finally destroyed it. Since its droppings polluted the leaves of the mulberry on which the silkworm feeds, and as healthy animals thus devoured them, and contracted the same disease, a single infected silkworm was capable of destroying a whole school of worms, and preventing the subsequent cultures from being developed.

M. Pasteur then laid down the rule that, in order to avoid the silkworm disease, it was necessary to choose with extreme care the animals which were to be employed for breeding. With this view he devised the following procedure:—When the female has laid its eggs it is at once destroyed. If a single corpuscle is found in its tissues, when crushed in water, the eggs are immediately burned. In the same way the several eggs of each hatching are carefully examined. If no corpuscles are discovered, the whole brood is preserved for culture; if any are found, the whole are immediately destroyed. Since that time the silkworm breeders have followed the rules of M. Pasteur. The implements for the purpose of recognising the diseased worms consist of a microscope, two objectives, one with low power, and one with high power, magnifying about 400 times, and a small porcelain mortar for crushing the tissues of the worm or its eggs, some glass slides, and a flask of distilled water. By this application of scientific research to the silkworm industry the silkworm disease has been almost wholly put an end to. Nearly all the silkworm growers, whether masters or servants, have learnt, by the aid of a very cheap little handbook, prepared by M. Pasteur, to recognise diseased worms or eggs from healthy eggs or worms, and thus a great industry, which was threatened with extinction, has been saved from the fate which threatened it.

(5) *Fowl Cholera*.—After having demonstrated that this affection is caused by a micrococcus, M. Pasteur showed that if this micrococcus is cultivated in the manner which he indicates, and the micro-organism thus obtained inoculated in a fowl, the fowls so vaccinated become proof against fowl cholera, even when they are placed in the midst of other infected fowls. These researches have a special and suggestive scientific interest, for he has shown that if you filter through plaster the liquid taken from one of the external foci of the disease in a fowl affected with fowl cholera, the filtered liquid thus inoculated will not give a healthy fowl the specific disease, but render it somnolent

and inert for some hours, so that it may be concluded that the micro-organism secretes a material to which must be attributed the lesions which are observed in fowls suffering from fowl cholera.

Some idea may be obtained of the commercial value of the work done by M. Pasteur in his laboratories from the following facts and figures, which I have on good authority:—In three departments of the centre of France, after the silkworm disease had attacked the factories, the product yielded a value of less than 1,500,000 francs. Since the regulations laid down by Pasteur have been applied, the average value per annum, calculated on five years, in those departments has risen to more than 22,000,000 francs.

As to wine, there was a known loss of wine to the extent of 1,700,000 francs in four departments. Since heating on Pasteur's method has been applied, there has been saved of this loss at least 1,500,000 francs; the difference of 200,000 francs being alleged to be due to the carelessness or ignorance of small proprietors, who are unwilling to heat their wine. As there are in France about forty-five departments that make wine, the saving may thus approximately be estimated. I should add that there are twelve departments that make silk.

In respect to anthrax, the following was the official statement indicating the ravages made by this disease in France and foreign countries, and the reduction of mortality effected by these inoculations:—

1881	Sheep	Oxen	Horses
France	62,050	5977	142
Foreign countries...	12,500	1254	100
Total	74,550	7231	242
1882			
France	270,040	35,654	1825
Foreign countries...	36,830	6,169	200
Total	306,870	41,823	2025
1883			
France	268,205	26,453	371
Other countries ...	84,825	5,777	975
Total	353,330	32,230	1346

The average mortality reduced by these inoculations in the proportion of 10 to 1 for sheep, and 15 to 1 for oxen, cows, and horses.[1]

Meteorological Laboratory.—The corresponding exhibit was that of the meteorological laboratory by M. Miquel, corresponding to which I hope to see a permanent meteorological station established as a sequel to the Exhibition. The work of M. Miquel has been summarised in the following words by Dr. Vivian Poore:—The observatory for Montsouris was established, in 1871, by the influence of M. Dumas, who was then President of the Municipal Council of the city of Paris. In 1873, M. Marié Davy was appointed director of the observatory by M. Thiers. The work of the observatory is as follows:—

(1) Meteorology proper, and its application to agriculture and hygiene. This department is under the control of M. Léon Descroix.

(2) Chemical analysis of the air and rain, under the control of M. Albert Lévy.

(3) The microscopic study of the organic matters held in suspension in the air and rain. This is under the control of M. P. Miquel.

In 1876, the municipality decided to have the above meteorological observations, in their relation to hygiene, made in different parts of the city. The chemical analyses and microscopical examinations are made—

(1) On drinking waters.

(2) On the waters infiltrating the soil.

(3) On the emanations from the soil and sewers.

(4) On the air of different localities estimations are made. A. (air), ozone, carbonic acid, ammonia, organic nitrogen; and similar analyses are made of the soil-water, &c. Every year the *Annuaire de Montsouris* is published, a work full of information, and which is now in its thirteenth volume.

The laboratory of Mr. Cheyne at the International Health Exhibition was largely fitted up by the aid of Dr. Koch, and of Dr. Koch's laboratory at Berlin. Mr. Cheyne has furnished me with the following outline:—

Dr. Koch's laboratory is subsidised by the Government. It consists of director, library, biological department under Dr. Koch and several assistants, and a chemical department. All expenses of investigation are paid. Koch's salary is only 300*l*. Other salaries I do not know. When appointed, Koch first set to work to improve methods of cultivating and studying bacteria, and to devise new methods, and the result has been a precision and simplicity in this sort of work quite beyond all expectation. His further researches have been devoted to the study of the cause of disease in man and how to prevent it. Either by himself, or under his direction, the causes and means of prevention of tuberculosis, consumption, erysipelas, osteomyelitis, and glanders have been absolutely demonstrated, while a large amount of work has been done in respect to the causation and prevention of typhoid fever, cholera, diphtheria, and other affections. His researches on disinfectants and the best mode of disinfection are classical, and are still being carried on. This work is being rapidly extended to other diseases, while important researches are going on relating to water, air, and soil.

The Anthropometric Laboratory at the Health Exhibition was designed by Mr. Galton, to show the feasibility of performing, at a small cost, an extended series of measurements of the human faculties, and of testing the demand that there might at present be for having such measurements made. The ulterior object he had in view was to familiarise the public with the facility and need of periodically recording facts which test the progress of individual growth and development, whether it is proceeding normally or otherwise; and if it should be abnormal, to call attention to the existence of hurtful influences, and to demand inquiry into their nature, and whether they may not be removable. The experience of the laboratory showed emphatically, first, that about seventeen different measurements of each person, including height, weight, strength, breathing capacity, eyesight, judgment of eye, hearing powers, &c., could be accurately performed at a cost of less than 3*d*., by means of a well-organised method of work; secondly, it showed that the public greatly valued the opportunity of having themselves measured and appraised in so minute a manner, inasmuch as the door of the laboratory was besieged all day long by a crowd of applicants for admission, far more numerous than could be accommodated in its small area, 36 feet long by 6 feet wide. As it was, measurements were made of between nine and ten thousand persons, yielding data that are now being discussed, and which have considerable statistical value. The methods and appliances used and suggested by the experience of this laboratory have been very recently described by Mr. Galton at the Anthropological Institute. It is therefore not necessary here to go into details. It may be taken as established that there need not be the slightest difficulty in periodically measuring with much completeness and keeping a register of the development of every boy and girl in large schools, at the cost of a very few pence per head per annum, on the supposition that the process was methodically conducted by a paid expert, with the willing and gratuitous assistance of the masters and attendants. The power of a system of periodical measurements and tabulated returns upon the well- or ill-being of the growing portion of our race is of unquestionable value, and it would seem that common-sense considerations must insure its being ultimately called into action. Now that there are signs of much awakening to the importance of such records, a central institution becomes especially desirable, where the best patterns of instruments should be kept, where instruction in their use might be obtained, where the methods of tabulation, and of quickly getting useful results out of the data, might be learnt, and where the fullest information of all kinds on anthropometry would be stored. It must not for a moment be supposed that anthropometry is a simple and thoroughly understood art. On the contrary, it continually grows, new methods being discovered from time to time of measuring faculties that had before escaped measurement. There can be little doubt that the progress of the useful art of knowing one's self all round, and of knowing others accurately, of reducing what has hitherto been too much a matter of estimate to quantitative measurement, would be very largely aided by the establishment of an anthropometric laboratory in a national hygienic institution.

Proposed Disposal of Surplus.—That which I look forward to, then, as the best possible sequel to this Ex-

[1] In the last thirty years there has been an increase of life-duration of from 39·9 to 41·9 years, an increase of 5 per cent. human duration of life. The annual economy of life, on the least favourable calculation, during the last five years, has been equal to a saving of 36,000 lives per annum. The money saving on the last five years has been calculated, on good basis, by Capt. Galton, to be in London alone nearly half a million of money per annum.

hibition, is the establishment of these laboratories, so vastly important to the prevention of disease and the maintenance of our population in health, and of the library on a permanent footing and under suitable direction. The whole subject is one on which I can only venture to express, thus far, my individual opinion, although I have the satisfaction of knowing that the views which I have thus put forward have met with considerable approval among many of my colleagues, to whom I have submitted them *in limine* for future consideration by the Executive Council, who may possibly approve of them, and in that case may feel it their duty to submit them to his Royal Highness the President, with whom will rest the ultimate decision as to the disposal of any parts of the surplus. The rumour that such a project was about to be submitted to the Council, has awakened the liveliest interest and satisfaction amongst the authorities of the leading sanitary associations in this country, and I am glad to know that the authorities of the Parkes Museum, of the Sanitary Institute, of the Social Science Association, of the Society of Medical Officers of Health, and of the National Health Society, have each, on their own individual motion, taken the opportunity of expressing, by resolutions and memorials, their strong sense of the great national value which they consider would attach to the accomplishment of this design. Should this proposition prove acceptable to the authorities, there is no doubt that the opinion of the great body of persons interested in the sanitary progress of this country, thus early expressed by the official representatives of every form of sanitary progress, would declare itself strongly in favour of an institution from which considerable results might be anticipated in the furtherance of health education, and of our knowledge of all that relates to the prevention of disease. It is further hoped that an Institute of Public Health, founded on this basis, might prove a home and centre with which these numerous voluntary organisations now working for the public health might connect themselves, by some well co-ordinated and accepted plan; that it might be a centre where their members would be able to meet; where libraries, class-rooms, and meeting-rooms might be made to serve a valuable purpose in bringing these various societies into closer relation. There is reason to hope that many of the great scientific associations which now foster the progress of science by grants to individual workers, would heartily welcome the establishment in this country of what it so greatly stands in need—a place of higher education and research in sanitary science, such, as I have already pointed out, as have been recently created in France and Germany. England has been first in sanitation; it is here that have been solved—so far as they have as yet been solved—many of the greatest problems of sanitary science; but we must acknowledge that, during the last decade, each of these countries has made progress in the higher departments of sanitary education and sanitary research, in which we can hardly be said to have held an equal place. This reproach we may now find the means of wiping away, and I earnestly trust that this may prove to be a sequel of the International Health Exhibition, than which no higher memorial could have been hoped for or expected.

The Lesson of the Exhibition as to Open-air Recreation and the Electric Lighting of Public Parks.—Let me conclude by reference to another aspect of the teaching of the Exhibition, less scientific, but yet of peculiar public importance. It was often said by the public scorner—a person from whose judgments and criticisms we have commonly much to learn—when walking through the crowded course of the Exhibition devoted to food and all that concerns the construction and decoration of the dwelling: "This is a Health Exhibition—where is the health?" and the popular answer was, "Outside in the gardens." That answer also I accept. I think you will agree with me that the practical demonstration which this Exhibition afforded of the eagerness of the English people to resort to healthful means of outdoor amusement was in itself a valuable result and an important experience. The gardens, illuminated by the electric light and enlivened by music, were undoubtedly a great attraction to the Exhibition, and I would be quite willing to agree with any one who might say that they were the greatest attraction. Allow me to add that I look upon this not merely as a means, but itself an end. It is no small thing to have acquired the conviction that our open spaces may be, and should be, much more largely devoted to the open-air recreation of the people than they are at the present moment. I say this now, without any intention of entering upon that large question, but with the specific desire to repeat (for it is only by repeating often that one can gain access to the minds of the majority who are all-powerful in such questions) that it appears to me to be no small disgrace to this great metropolis that, in the very centre of its crowded districts, within an arrow's flight of the houses probably of most of us who are here, there lie great open spaces, such as Hyde Park (but what I say refers also to Victoria Park), which at night are dreary desolate areas of darkness, which are unlighted, which are dangerous to cross, which are unused in the evenings for any wholesome or moral purpose, which are often scenes for the display of some of the worst vices incidental to the lowest dregs of the population of the great city. Why should we not learn from the success of the music and the lighting of the gardens of the Health Exhibition, that our great parks should all be lighted by the electric light at night, and that throughout the spring and summer months the military bands should play there, and should make those places, which are now not only useless but scandals to the metropolis, the sites of healthful and innocent recreation? I have inquired from a good source what would be the cost of lighting Hyde Park by the electric light; and I am not speaking without data when I say that I believe that Hyde Park could be adequately lighted with the electric light, so that it might add to the resources of health and enjoyment for the teeming population surrounding it, at an annual expenditure of about 5000*l*. I do not know what impression this will make upon you. I confess that to me such an expenditure seems trifling in consideration of the sum of human happiness and enjoyment, and, I may add, also of health, which such a devotion of municipal or public money would afford to the people of this city. Nor is it likely that, the example once set, it would end here. Our eastern population have a right to the enjoyment of their parks in the evenings that could be conceded to the west. This lesson also, then, the Exhibition seems to me to teach, and how greatly we might all rejoice if it should ultimately prove that the lighting by electric light of our public parks, and the introduction of music as a part to enliven and attract the people, and to add to the success of the innocent recreation, the health and the happiness of our working population should form also one of the possible sequels of this Exhibition.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Prof. Roy was on Thursday last admitted to the degree of M.A. *honoris causâ*. The Public Orator in presenting him spoke as follows:—

Dignissime Domine, domine Procancellarie, et tota Academia, —Quis nescit Athenas illas Caledonicas, cum aliarum artium, tum praesertim studiorum medicorum praeclaram esse sedem. Academiae tam illustris alumnum, Pathologiae Professorem primum nobis nuperrime datum, hodie senatus totius nomine salutamus, ipsum senatorum nostrorum ordini libenter adiungimus. Neque vero una tantum doctrinae sedes Professorem nostrum sibi vindicat; scilicet Germaniae ipsius Academiae celeberrimae hunc virum inter alumnos suos numerant. Ne inter Cantabrigienses quidem prorsus hospes est, qui non modo Physiologiae praeceptoris nostri optimi experimentis aliquamdiu interfuerit, sed etiam ipse de Physiologiae arcanis praelectiones quasdam inter nosmetipsos habuerit. Idem quondam (ut ad remotiora transeamus) Ottomannorum inter milites arti medicae deditus, in ipsa Epiro, prope Pindi montes, prope Dodonae antiquae diu desertum oraculum, velut ἰατρόμαντις aliqui, consulentibus respondebat. Ad eundem postea Respublica Argentina, morbo gravi et inexplicabili oppressa, velut ad oraculum aliquod misit, cuius responsis obsecuta peste illa dira sese protinus liberavit. Inter antiquos quidem victimarum in visceribus rerum futurarum praesagia quaerebantur; hic autem, non vanus haruspex, ex ipsis morbis quos alii reformidant, ex ipsa Morte quae aliis tacet, veritatem ipsam audacter extorquet,—adeo ut Catonis verbis profiteri possit:

me non oracula certum
sed mors certa facit.[1]

Vobis praesento Medicinae Doctorem Edinensem, Pathologiae Professorem Cantabrigiensem, CAROLUM SMART ROY.

[1] Lucan, "Pharsalia," ix. 582.

SOCIETIES AND ACADEMIES

London

Physical Society, November 22.—Prof. Guthrie, President, in the chair.—Mr. James Bewsher was elected a member of the Society.—The following notes were read by Mr. R. T. Glazebrook, M.A., F.R.S.:—On the permanence of some standards of electrical resistance. The author has had occasion to compare with ten standard B.A. units a coil which had been tested by Lord Rayleigh in 1882, the coil then being two years old. He found that its resistance was 9·98335 B.A. units at 14°·05 C., while Lord Rayleigh found the value 9·98330 B.A. units. Thus, either the coil and the standards have changed by exactly the same amount, which is improbable, for they are wires of different thickness, or they have all remained permanent.—On the effect of moisture in modifying the refraction of plane-polarised light by glass. The author described some experiments he had been engaged in lately at the Cavendish Laboratory. Plane-polarised light is made to fall on a plate or a wedge of glass at various angles, and the position of the plane of polarisation determined. It is found that this depends greatly on the hygrometric condition of the air in the neighbourhood of the glass. If moist air be blown on to perfectly clean glass, the plane of polarisation of the emergent light is displaced from its normal position in one direction, while, if dry air be blown, it is displaced in the opposite direction. At an angle of incidence of 60° the difference between the two positions is from 6′ to 8′. If, however, the glass be not perfectly clean, the effect of moisture is *at first* the same as that of dry air, though on stopping the draught an opposite effect is observed. The author assigns as the cause of this the heating of the surface, which, as Magnus discovered, is produced by a draught of moist air. He finds, on repeating Magnus's experiment, that the heating is not produced if the glass be clean, and he shows by an independent experiment that slight local heating does produce an effect on the plane of polarisation in the same direction as that due to the dry air.—Mr. Glazebrook also exhibited a spectrophotometer described by him in a paper read before the Cambridge Philosophical Society (*Proc. Phil. Soc.* vol. iv. part vi.), and made by the Cambridge Scientific Instrument Company from his design.—A note on a point in the theory of pendent drops, by Mr. A. M. Worthington, was read by the Secretary, Mr. Walter Baily. This was a note upon a paper recently communicated by the author to the Royal Society upon the measurement of the surface-tension of a liquid from the observations of the forms assumed by pendent drops. By making a measurement of a horizontal section of such a drop, and of the angle made by the tangent plane to the surface at the line where the section meets the surface with the horizontal, and knowing the density of the liquid, sufficient data are obtained to determine its surface-tension. Prof. Perry remarking upon this paper gave an account of some researches upon the subject, in which some years since he had assisted Sir William Thomson. On the usually accepted theory of surface-tension based upon the behaviour of liquids in capillary tubes, at every point of the surface of a liquid the equation

$$kp = \frac{1}{R} + \frac{1}{R'},$$

must hold where p is the pressure at that point or the difference of pressure on the two sides of the surface, R and R' the two principal radii of curvature, and k a constant. In the case of a drop whose surface is one of revolution about the vertical, the contour may be drawn from the equation. This was done, and theoretical drawings were made of a number of drops. These have since been compared by Sir W. Thomson with enlarged photographs of actual drops, and the results are highly satisfactory. This law no longer holds in the case of a drop at its "critical point," or that point when it is about to fall, since here dynamical action comes in.—Mr. Baily also read a paper by the same author on a new capillary multiplier. This is an apparatus for the measurement of surface-tension, and is a modification of one used by M. Despretz. From one extremity of the arm of a balance is suspended a roll of platinum foil, consisting of a strip 50 cm. long and 5 cm. or 6 cm. broad, rolled up, the successive convolutions being prevented from touching by rolling up with the foil a number of small pieces of hard glass tubing about 2 mm. diameter, which occupy the upper part of the helix, and preserve the form of the lower. The coil is cleaned by igniting it in a Bunsen flame, and then suspended with its lower end in the liquid to be examined. The increase in weight corrected for the part of the coil immersed is due to the fluid rising between the convolutions. From this the surface-tension is readily calculated.—Mr. Hilger described a new solar eye-piece. In Prof. Pickering's eye-piece there are two rectangular prisms of glass of slightly different refractive indices. The light of the sun undergoes partial reflection at the surface separating the two prisms, the ratio of the reflected to the incident light diminishing with the difference between the refractive indices. It is found, however, that such a prism under a high power always gives a double image, due to the two glass surfaces, it being practically impossible, even under enormous pressure, to bring them into true contact. To obviate this Mr. Hilger makes the second prism of Canada balsam, which gives the most satisfactory results, the image being pure and single.

A TEACHING UNIVERSITY FOR LONDON

A MOVEMENT, which first began to shape itself into form at the Educational Conference at the Health Exhibition, made its first formal public appearance at the house of the Society of Arts on Monday afternoon. The crowd of well-known and much-occupied men with which the room was filled was at least an earnest of something more than a discussion of a mere speculative project; and the speeches made, though revealing, as might be expected, a considerable diversity in point of view, were listened to with a closeness of attention which indicated a pretty confident belief that the movement was not likely to evaporate in mere debate.

Lord Reay opened the proceedings with an address, which was admirably conceived both in tone and matter. If subsequent speakers scarcely can have been said to have carried on the discussion on the same level, this may be attributed to the fact that the report submitted to the meeting for adoption by Lord Justice Fry embodied an amount of detailed suggestion which the meeting was naturally not in any way prepared to assimilate without a good deal of consideration.

Every one knows that we have in London a body bearing the title of a University. Every one, at least who has looked into the matter, knows equally the immense services which this institution has rendered in raising the standard of middle class education. But a University all the same, in any intelligible sense, it is not. It is essentially nothing more than a Government Department for giving, after examination, academic certificates. Nor, as Professor Lankester very properly pointed out, is it, any more than the Home Office for example, an institution which, because its head-quarters happen to be in London, is locally identified with the metropolis in the same sense in which the Universities of Oxford and Cambridge are identified with the places in which their work is carried on. The operations of the University of London are, in point of fact, more wide-reaching than those of any other Government office, and are, indeed, co-extensive with the Empire itself.

In one aspect the whole movement may be regarded as an outcome of the nascent municipal feeling in the life of the metropolis. The Examining University, for reasons stated above, does not, and in its present form never can, satisfy the reasonable desire that the metropolis should possess that academic crown which is worn by every other great capital in the world. The disembodied spirit of what might be brooding over gloomy examination halls may strike a wholesome terror into the hearts of candidates, and sustain a certain feeling of emancipation in the hearts of candidates; but it cannot, and does not, excite any enthusiasm in either. Nor has the cold officialism of Burlington Gardens ever treated with more than a lofty disdain the more humanly organised institutions which furnish the victims who pour into its portals.

The movement to constitute a Teaching University is undoubtedly in some degree due to a reaction against this state of things. Those whose business "is to teach, know now-a-days that a great deal depends on the way teaching is done. It is here that the educational bodies of the metropolis feel their isolation. There is no central authority to gather their representatives into its fold and smooth away the individual difficulties in the way of common action and" bringing into harmonious cooperation the dual business of examination and teaching. Life is getting appreciably shorter now; the thread of existence has more knots though its length remains the same. The time that can be given to education out of an ordinary existence cannot be indefinitely expanded. Method must be brought in to economise labour in instruction. This is a very different thing to cramming; it is on the contrary a scientific mode of directing the educational attack in the most effective way. Here the rulers of the University have shown themselves most deficient in sympathy; they have turned an obdurately deaf ear to the entreaties which have been repeatedly addressed to them by the Convocation of the University to get "touch" with the teaching bodies. And, what is perhaps even still more irritating, though, as remarked at the meeting, for the most part, laymen in education, they still issue in a purely *doctrinaire* spirit directions which of course from the nature of the case have the binding force of edicts at the actual seats of education. Dr. Carpenter, with an official optimism excusable enough in one who has devoted a lifetime to loyal and honest work, contended, it is true, that the university was blameless in this respect. But those who are familiar with the other side of the shield know how far this is from being the feeling in teaching institutions. Manchester has already broken away from the rule of Burlington Gardens, and it can scarcely be doubted that had the University of London shown a more conciliatory attitude with regard to the formation of Boards of Studies, the present movement would in all probability have taken a very different shape.

It is proposed, then, alongside of the existing examinations to have a Teaching University. This it is also intended should examine and grant degrees. It may be thought that this is going too far, and that it is not desirable that the one thing should become a mere mechanical reflection of the other. But the risk is small; the principle is now-a-days accepted by all who have really studied the matter, that teachings and examinings must be in the hands of the same persons; but this does not imply that the same individuals should control both. Nor, it must be admitted, is this merely a matter of interest to the teaching bodies. The imperfect educational discipline to which a large proportion of the candidates who frequent the examination rooms of the university have been subjected, leads to an inordinate amount of rejections. This creates the misconception in the public mind, that the examinations are unreasonably severe. The real fact is that the candidates are badly prepared. In this way the want of cooperation between teachers and examiners becomes indirectly a real obstacle to educational progress.

So far we have endeavoured to give our readers an account as distinct as we have been able to gather of the forces which have initiated this movement, and the aims which are desired by it. We cordially sympathize with both, and it is because we do so that we must now indulge in a little criticism on the scheme as put forward by Lord Reay's committee. In the first place, we found it difficult

to believe that the creation of a new university with full powers in the metropolis is ever likely to come within the bounds of political possibility. It is not that the Government will be inaccessible, but that it will be difficult to persuade general public opinion of the necessity of such a course. We believe that it will in the end be necessary eventually to come to terms with the existing university. The fact that eleven members of its Senate have joined the movement, shows that that body at any rate contains a powerful element discontented with its present asphyxiation by red tape. What, however, we do hope to see is the federation of our scattered educational bodies in London into Faculties, which would be practically universities in all but the name, and the representatives of which should have a leading voice in the management of the Central University. The only speakers who really evinced at the meeting a clear idea of their own policy, were the representatives of the Medical profession. Prof. Marshall showed with singular lucidity that the altered character of medical education has made the continued isolation of the smaller medical schools a practical impossibility. Not merely has technical instruction gone beyond the capacity of the junior members of the medical staff who are usually told off for it, but the appliances required are too costly for all but the wealthier schools to provide efficiently, and the teachers are themselves wanted for the more minute and careful clinical instruction which is now everywhere demanded.

The Medical Schools will therefore combine, perhaps, into some four great groups, for purposes of education and the organisation of laboratories, just as the small colleges at Oxford and Cambridge have combined for purposes of intra-collegiate lecturing. Once federation has begun, the foundation of a medical faculty for London is only a question of time. This will come about, probably, whatever the fate of the more general movement. But such a faculty would undoubtedly be found to be politically a body to whose just claims in direct medical education the University of London would find it impossible to lend a deaf ear.

The faculty of law may also shape itself into existence, though, it must be admitted, the elements of its form are, at present, very dim and shadowy.

To balance these we want a faculty of literature and science, and the materials for these are to be found in a federation of University and King's Colleges, as suggested by Prof. Lankester. If the representatives of such a faculty were allowed a proper share in the councils of the existing University, it is not obvious why such a federation should be intrusted with a separate degree-giving power.

We now come to what appears to us the weak point in the scheme. A university may impart knowledge; it may test its quality when imparted; but that which has ever been the peculiar glory of university life, is to enlarge its bounds. But except a few well-expressed sentences which fell from Lord Reay, and a sentence put into the conclusion of the report very much with the air of an afterthought, this very important matter does not seem to have received very much attention. Now the most melancholy feature about such elements of university organisation as already exist in London, is its displayed incapacity to retain its best men. There is an obvious dearth of such posts as would satisfy their legitimate ambition. No sooner amongst us does a man rise to the first rank at any seat of education, than sooner or later he is drafted off to one of the universities in the provinces. To take the first instances that come to hand: Cambridge has robbed us of Michael Foster, and Oxford of Burdon Sanderson, while the greatest biological teacher of the day is driven from England by ill-health after a life toilsomely spent in the lowest order of teaching—drudgery. What is absolutely essential to add lustre and distinction to the work of a Metropolitan University is a body of University Professors who would take charge of the higher studies, which never can be properly cared for by bodies sedulously occupied with the very serious business of the higher education. What we hope then some day to see is the University of London equipped with a proper staff of Regius Professors, who themselves would be at the least an invaluable bond of union between its own too abstract isolation and the living reality of the actual teaching bodies.

Although we could have wished for greater insistence on this—as it seems to us—most vital point, we cannot but entertain the highest hopes of the usefulness of the present movement. It has some of the notes of healthy organic development; it has at least spontaneity and individual activity, which have always been the foundations of political achievement amongst us. At the worst, mere effervescence is better than stagnation, and we think there is more in this movement than effervescence. In any case we cannot too warmly tender our expression of acknowledgment to public men like Lord Reay and Sir George Young, who have spared neither pains nor labour in the purely patriotic labour of giving our own too inarticulate murmurings definite form and expression.

THE POLYZOA OF THE "CHALLENGER" EXPEDITION

The Zoology of the Voyage of H.M.S. "Challenger." Part XXX. "Report on the Polyzoa—the Cheilostomata." By George Busk, F.R.S., V.P.L.S., &c. (Published by Order of Her Majesty's Government, 1884.)

THE description of the Polyzoa collected during the expedition of the *Challenger* was undertaken by Mr. Busk, and the first part of his Report, comprising the Cheilostomatous forms, or those in which the mouth of the zoœcium or cell is provided with a movable lid which shuts down over the polypide when retracted, has just been published.

The investigation of this important part of the *Challenger* collections could not have been placed in better hands. As an authority on the zoology of the Polyzoa, Mr. Busk stands pre-eminent; and the present admirable Report of 216 pages and 36 plates bears testimony to a laborious and conscientious investigation, the value of which as a contribution to our knowledge of the multitude of forms associated under the name of Polyzoa cannot be over-estimated.

The number of species of Cheilostomatous Polyzoa in the *Challenger* collection is 286, and when these came into Mr. Busk's hands he found no less than 180 of them

new. In one genus alone, that of the *Reteporæ*, the number of known species has been raised by the dredgings of the *Challenger* from 31 to between 50 and 60.

The determination and definition of species in a collection so large as that of the *Challenger* Polyzoa, and in a group of organisms in which the differences are far from being always strikingly obvious, cannot but be a work of great labour. The critical examination of the species in such a genus as *Retepora*, for instance, which is represented in the *Challenger* collection by 23 species, and *Cellepora*, which is represented by no fewer than 31, requires no ordinary patience, and the author must be congratulated on having so far brought to a conclusion labours which, in order to be conscientiously performed, must be often wearisome and monotonous.

Among the most important contributions of the Report to the systematic zoology of the Polyzoa is the revision which it contains of *Adeona* and allied genera. A critical comparison of the species of *Adeona* with species belonging to other genera which had been hitherto placed among the *Escharidæ* has necessitated the founding of a new family, *Adeoneæ*, in order to include the whole in a single natural group. This family has several peculiarities, among which the most interesting is the possession by all the species of three different kinds of cells, which the author terms zoœcial, oœcial, and avicularian. Oœcia of the ordinary type are entirely absent, and their function appears to be performed by special cells which differ in form from the others. When decalcified these oœcial cells appear as thick-walled sacs, containing in most cases an ovoid mass, which resembles the contents of an ordinary oœcium, and like these is almost certainly embryonal. Mr. Busk has further made the important observation that in some of them there is lodged instead of this mass a polypide similar to those inhabiting the zoœcial cells, and he concludes that the embryonal mass is derived from a polypide, which it finally replaces.

Among other peculiarities of the Adeoneæ is one which, notwithstanding its apparent triviality, derives importance from its constancy. This consists in the universal presence of a projecting point at each end of the base in the avicularian mandibles both large and small. In doubtful fragments this character alone will often indicate the affinities of the species.

The descriptions of the new species are throughout the work drawn up with that care and precision which characterise all Mr. Busk's zoological writings, while the absence of redundant description and the exclusion of characters not necessary for the diagnosis, give to his definitions a conciseness which will be appreciated as it deserves by all who require to consult the Report.

In a large proportion of the diagnoses the author has had recourse to the chitinous elements of the skeleton. These are the so-termed opercula or oral valves, and the chitinous parts of the avicularia and vibracula; and a very large number of accurately-executed outlines are given in order to show the various forms assumed by these elements in the different species. The employment of the chitinous elements in the classification and descriptive zoology of the Polyzoa is due entirely to Mr. Busk, who has convinced himself that "their value for these purposes cannot be over-rated, while their importance extends far beyond the mere distinction of genera and species."

The descriptions of the species are of course necessarily confined to the hard parts, whether calcareous or chitinous, for, except in living examples, it is rarely possible to determine any facts of importance regarding the soft parts of the colony. The author, however, gives two highly instructive figures of the avicularia of *Bicellaria pectogemma*, in which the muscular apparatus and other soft parts of these curious and still enigmatical bodies are clearly and beautifully represented. In one of his figures of *Carbasea moseleyi* also—a form in which the calcareous walls are quite transparent—there is a very interesting view of the polypides in the interior of their cells.

The distribution of the species, geographical and bathymetrical, finds a prominent place in the Report. An instructive map is appended in which the oceans traversed by the *Challenger* are divided into seven regions, three being to the north and four to the south of the equator, each including 90° of longitude. In each of these regions the stations from which any species of Polyzoa were obtained are indicated.

The bathymetrical range varies within wide limits. The greatest depth which yielded any species to the dredge was 3125 fathoms, in the North Pacific region. From this vast depth four species were procured, and between it and quite shallow water a great number of stations of very various depths are recorded.

One of the most unexpected facts brought out in the Report is the very wide bathymetrical range enjoyed by certain species. Thus *Cribrilina monoceras* is one of the four species brought up from 3125 fathoms in the North Pacific, while the same species was obtained from 1325 fathoms in the South Pacific, from 69 fathoms in the South Indian or Kerguelen region, from 55 fathoms in the South Atlantic, and from 35 fathoms in the Australian region.

This striking difference in the depths inhabited by one and the same species is, however, exceptional; and so is the wide range of geographical distribution which is here presented by a species occurring at great depths. The study of the bathymetrical distribution of the *Challenger* Polyzoa shows that "the extent of geographical distribution is to a considerable degree correlative with the bathymetrical, the wider geographical distribution being in most instances coincident with the shallower depths."

To this law another striking exception is afforded by the beautiful genus *Catenicella*, a genus very rich in species, which, though from comparatively shallow water, are almost exclusively confined to the Australian region.

The thirty-six beautiful plates which illustrate the Report are all that could be desired. Clearly and faithfully drawn, they place in the hands of the zoologist facilities for the determination of the species which, with the descriptions in the letterpress, leave no excuse for erroneous diagnosis.

Though the Report is confined to the species obtained during the expedition of the *Challenger*, the number of these is so large, and the descriptions and figures so exact, that the work will possess a classical value, and be found indispensable by every student of the Polyzoa.

G. J. A.

OUR BOOK SHELF

On the Healthy Manufacture of Bread. A Memoir on the System of Dr. Dauglish. By Benjamin Ward Richardson, M.D., F.R.S. (London: Baillière, Tyndall, and Cox, 1884.)

THIS pamphlet is another of Dr. Richardson's labours in the cause of public health. It deals mainly, as the title implies, with healthy bread, and especially with the system of the late Dr. Dauglish of Malvern for baking what is now generally known as aërated bread. The advantages of the aërated process are stated by the author to be that the destructive influence of fermentation is prevented. There is no chemical decomposition of the flour whatever, and therefore no loss of material, while the rising of the dough is just as effectively carried out. The aërated bread contains, therefore, all the gluten and all the albuminous food of the wheat, out of which the living tissues are constructed, as well as the food which ministers to the animal warmth and vital activity. Moreover, much labour to the baker is spared, and the kneading by hand is wholly dispensed with—a matter of some consideration to delicate or fastidious persons. The gradual steps by which the process has been worked out, from the incubation of the idea in the brain of Dr. Dauglish to the modern aërated process of baking are fully traced by Dr. Richardson, who describes also the different effects of fermentation and aëration on the different qualities of flour, the economic and sanitary advantages of the new system to the workmen (by no means the least important part of the subject, as those who recollect Mr. Lakeman's report on the London bakeries, and who read Chapter IX. of this little work, will acknowledge), and the public advantages of the aërated bread in relation to health. An appendix contains a brief memoir of Dr. Dauglish.

Proceedings of the Edinburgh Mathematical Society. Second Session, 1883-84.

OUR readers have seen from time to time in our "Society" Notices the titles of papers read before this young but from the outset vigorous body, and must have often wished for a more intimate acquaintance with their contents (as the odoriferous steam issuing from the cookshop tempts the hungry "Arab" to enter and feed). We are glad to find, from the volume before us, that the Society is in a position to print its *Proceedings*, for we now know how interesting the papers are. They are not, like some other papers nearer home, caviare to the general, but they deal with matters which come home to every mathematical teacher. Mr. Mackay writes on the circles associated with the triangle, viewed from their centres of similitude; Mr. Muir, on the condensation of a special continuant; Dr. Macfarlane, on voting; Prof. Chrystal, on an application of matrices to spherical geometry, on a problem in partition of numbers, &c. Mr. Allardice furnishes some useful notes on spherical geometry and trigonometry; Mr. Browning, some illustrations of harmonic section; Mr. Barclay, notes on the teaching of elementary geometry (abstract only), and Mr. Traill, proofs of the theorems as far as "Euclid" i. 32, from first principles. Other papers are: a good concise account of Pascal's "Essais pour les Coniques" by Mr. Macdonald; the hypothesis of Le Bel and Van't Hoff, by Prof. Crum Brown; on the representation of the physical properties of substances by means of surfaces, by Mr. Peddie; and a joint account of the problem "La Tour d'Hanoi" (one of displacements), by Messrs. Allardice and Fraser. With these *Proceedings* are bound up Prof. Tait's introductory address on Listing's "Topologie," which, our readers will remember, has been published in the *Philosophical Magazine* (January 1884, pp. 30-46, with plates), and Mr. Muir's Presidential Address entitled "The Promotion of Research; with Special Reference to the Present State of the Scottish Universities and Secondary Schools" (delivered February 8, 1884).

Elementary Text-Book of Trigonometry. By R. H. Pinkerton, B.A. (London: Blackie and Son, 1884.)

THIS elementary text-book of 176 pages contains all the essentials for obtaining a knowledge of trigonometry proper. It might be used either by those who desire merely a thorough grounding in the elements, or, as a first book, by those who intend to take a full analytical course. The arrangement is good, the text well written, and the examples, worked and unworked, are numerous and judiciously chosen. The introductory chapter on the measurement of angles is particularly commendable. We should prefer, however, not to write "$\pi/3$ radians" but "$\pi/3$ radian," reading it "*pi*-thirds of a radian." It may be suggested also to a writer who has the courage to introduce reforms, whether the time has not come for dispensing with the so-called *tablogsines*, *tablogcosines*, &c., and using only logsines, logcosines, &c. *Tabular* log functions are, according to our experience, well-meant aids which only hinder.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Iridescent Clouds

ON Thursday evening, December 11, about fifteen minutes after sunset, in the south-west direction as seen from the Royal Observatory here, were two rather large clouds about 10° or 12° high, and below them several much smaller ones, all of them of the most brilliantly iridescent colours and nothing but bright colour, of a kind I do not remember to have seen before, though they were not improbably like some described by several of NATURE's correspondents last year.

The principal cloud, some 5° or 6° long and 2° or 3° across, exhibited a diagonal band of glowing green, passing through blue into exquisite violet on either side, while it was fringed nearly all round by dull red.

The second largest cloud, a little below and rather to the eastward of the first, exhibited all the same colours in similar diagonal bands, but unconformably with the places of the bands of the first produced down to it; though both may have had their bands at right angles to a ray from the sun long since set, but directed on their centres. The sky behind them and all around was singularly dark and sombre, so that these iridescent clouds, in the brightness and richness of their colouring, reminded one more of mother-of-pearl inlaid in a black tea-tray than any ordinary sunset sky.

The smaller clouds of the same kind lower down gradually lost the central green band and passed into yellow and orange, but were still phenomenally bright specks of luminous material on the dark general background. All this towards the south-west; while west and north-west the sky was nearly clear, and exhibited, in a sunset-illumined sky "proper," a fairly fine but quite ordinary set of thin cirro-stratus rolls of cloud, warmly coloured on one side and cold-gray shaded on the other, like any corporeal body in the same exposure.

Lower down still on the horizon was a heavy cumulo-stratus cloud, which the west wind presently brought up to eclipse the green and blue iridescent clouds, proving that they were higher than it, though not so high as the dark cirrus haze to the south-west that had served so well to set forth their brilliant and unusual colouring. C. PIAZZI-SMYTH

Edinburgh, December 13

A STRIKING phenomena, apparently a new phase of the cloud-glows, was widely witnessed here on the 13th, and I myself noticed it, though on a much less scale, and in the north-

east, on the 11th. About 3.30 p.m. the upper edge of a dark, very lofty haze cloud, stretching almost straight from alt. 15° in the south-south-west, to about alt. 20° in the north-west, was fringed with prismatic colours, in parts thrice repeated, separating the dark haze cloud from a bright white haze, like that often seen of late near the sun, which itself was nearly setting. The luminous haze was widest, about 5°, above the sun, and was also, but far more faintly fringed, with a hazy blue sky above. It lasted until 4.20, but at 4.10 the dull cloud was a deep violet, and the bright haze a steel blue. They both seemed to disappear in the dusk, but the bright glow reappeared about 4.40 p.m.

On both occasions the phenomenon lasted long after sunset, and the cloud was quite distinct from the feathery cirri on which, if near the sun, one so often sees prismatic effects. On the 11th the two small oblong clouds affected had the colours in regular bands, in one round a dark, in the other round a bright centre, reminding one of Newton's rings. J. EDMUND CLARK

York, December 15

The "New" Volcanic Island off Iceland

KNOWING the interest which, from their association with the later years of the Gare-fowl's existence, I have long taken in the islets lying off the south-west point of Iceland, Prof. Lütken has most kindly sent me a copy of the Copenhagen newspaper *Dagbladet* for the 7th of this month, containing an article by Capt. C. Normann of the Danish Royal Navy, in command of the ship *Fylla*, during her recent scientific voyage to Greenland, a distinguished officer and an eminent authority in Arctic matters. The article is long—too long for my powers of translation—but, with the friendly help of a Danish young gentleman of this University, I have mastered it, and find it exceedingly entertaining. It treats of the island which, as already announced in these columns (vol. xxxi. p. 37) and elsewhere, is said to have been lately thrust up, as other islands have before been known to be upthrust (at least temporarily) in that volcanic neighbourhood. According to the statement of Mr. Consul Paterson (*loc. cit.*) it is said to have been first observed by the lighthouse-keeper at Reykjanes on July 29; and it would seem that news of its apparition speedily reached Reykjavik; but unfortunately, says Capt. Normann, there was then no ship there available to make search for it. Rather less than a month later, however, the *Dupleix* and *Romanche*, of the French navy, arrived at that port, and the commander of the former, animated with the laudable desire to determine the position of the new island, and if possible to effect a landing upon it, resolved to do so in the course of his homeward voyage, and, with that intent, set out after a short delay. To the surprise of all at Reykjavik, he, as he subsequently informed the French Consul there, could find no trace of the object of his search on August 24. On the departure of the *Dupleix*, however, the commander of the *Romanche* dispatched two of his officers, equipped with proper instruments, by land to Reykjanes, thence to take the bearings of the new island. On August 26 they undoubtedly saw an island corresponding in position with what they expected to see, and reported accordingly to Reykjavik, where Capt. Normann's *Fylla* had arrived on the 25th, on her homeward voyage. The Danish commander, equally enthusiastic in the cause of scientific discovery, accordingly left Reykjavik early on the morning of the 27th, and soon after mid-day his ship was off Reykjanes, whence he pursued a course along the northern side of the bank from which the Fowlskerries emerge, seeing nothing of the new island, it is true, but that time the weather was thick. However, he passed cautiously (as well became a navigator in water liable to volcanic upthrusts) along the whole range, and even beyond the furthest of the emerged skerries—the Geirfugladrángr or Grenadeerhuen, when it began to grow dark, and also to blow. Next morning he turned back, running still along the northern side of the bank. It was clear and beautiful weather, and the rock just named, as well as Eldey or Melsække, the innermost of the range, stood out in bright sunshine. Breakers marked the position of the old Geirfuglaskér, which sank beneath the waves in 1830, and the neighbouring coast of Iceland, as well as the inland fells, was plainly visible, but nothing in the shape of a "new" island was to be seen. So he came back to about midway between the Meal-sack and Reykjanes—the lead giving a depth of eighty fathoms of water. Thence, thinking that after all there might be some mistake in the reported position of the island, he put his ship's head about, and ran along the southern side of the bank. But again was he disappointed, for no new island met the anxious gaze of all on board.

It remains to be said that a day or two later the *Romanche* came to the same spot, but alas, nothing new was to be found—not even a pumice-stone by which, as Capt. Normann remarks, all decent volcanic islands are expected to indicate their position, even when submerged. Still, the form of the "new" island went on gratifying the vision of the lighthouse-keeper at Reykjanes; and, as Mr. Paterson has told us (*loc. cit*) it was seen by him through a telescope on September 9. I do not for a moment doubt that both he and previously the officers of the *Romanche* saw what was pointed out to them as the "new" island; but, from all that has been said before, and from my own knowledge of the locality, gained during a two months' stay at Kykjuvogr and the neighbourhood in 1858, neither do I doubt that Capt. Normann is perfectly right in asserting that the supposed "new" island is a very old friend of mine—the Geirfugladrángr or Grenadeerhuen before mentioned—the outermost of the emerged Fowlskerries, and our best thanks should be given to that gallant and scientific officer for dispelling the mystery. ALFRED NEWTON

Overpressure in Schools

I HAVE carefully read Dr. Gladstone's article on over-pressure. Over-pressure is due more to the action of inspectors and teachers than to the requirements of the Code; *e.g.* a teacher in my district has a first class in an infant school, the children being all about six years of age. Owing to the unusual brightness of the children and their regular attendance, the teacher has had no difficulty in training her class in the three R's for first standard work, which, under ordinary circumstances, they could not do until they were a year older and in a higher class. What is the result? An inspector visits that school, finds the children can do much more than is required by the Code, and, without reflecting *how* this has been accomplished, he gives a good report for that class. The following week he visits another school in the same neighbourhood and examines a similar class; these children, he finds, are not so far advanced as those examined the previous week, and therefore he makes a less favourable report, thinking that the teaching-powers are not so good, although the children have really been quite as well taught, and are fully up to the requirements of the Code. When the report comes to the latter school, the teacher cannot understand how it is that the class has not gained the report it deserved, until by and by she hears indirectly what has been accomplished at the school previously examined. Then she says, "If they can do it at that school, we can do it here." Hence *over-pressure.* If inspectors did not examine beyond the Code, teachers would not train children for a higher standard than the Code requires.

Dr. Gladstone says, "Teachers used to be paid partly from the Government grant, and thus had a pecuniary incentive to press forward the feeble so as to insure a pass." That is quite true, but teachers will be found in the future to be quite as anxious as they were in the past as to the results of the examinations. They know quite well that now the salaries are fixed, and do not depend on results, it would be said directly that they did not take the same interest in their work as formerly if perchance the schools passed a less favourable examination, and on this point they are keenly sensitive.

Dr. Gladstone advocates "varied and appropriate occupations in infant schools." It is no doubt very monotonous for little children to be kept closely to the study of the three R's, but there are very few who really like the Kinder Garten as taught in our infant schools, unless it be the Kinder Garten games: it is *not* play, but hard work for such little ones to do. It is impossible for the work to be taught successfully when a teacher has too large a class under her control; in Belgium an assistant mistress has a class of fifty children with a pupil teacher to help her, and then no doubt Kinder Garten can really be carried out with beneficial results to the children, but in the London Board schools, where an assistant teacher has seventy or eighty or even more in her class *without help*, how is it possible to obtain good results? If Kinder Garten is to be taught with success there ought to be a Kinder Garten mistress appointed by the Board to teach it to the children, and I think there are very few teachers who would not agree in this. Of course it would entail extra expense, but it would be an expense more beneficial to the

children than some that are indulged in. These I believe to be the views of nearly all teachers as well as those of myself, who am but a SCHOOL TEACHER

December 8

The Tokio Earthquake of October 15, 1884

AT 4h. 21m. 54s. a.m. the inhabitants of Tokio were awakened by a sudden and violent earthquake. In Yokohama, which lies about sixteen miles south-west by south from Tokio, the disturbance was noted at 4h. 21m. 38s., that is to say, sixteen seconds before it was felt in Tokio. The chief source of error in these time-records—if error exists—will probably be due to observers at different stations having noted time at different portions of the disturbance, the length of which, as determined by the sensations of those who made the records, was about one minute, but, as recorded by a seismograph, between five and six minutes. At the commencement of the disturbance four complete waves were described in three seconds, but at the end of the disturbance the motion became so slow that each wave occupied from two to three seconds. From a record taken by Mr. K. Sekiya, a gentleman whose especial duty it is to attend to the earthquake phenomena of this country, it would appear that the maximum range of motion may have reached 42 mm. The maximum acceleration per second per second was about 500 mm., that is to say, the intensity of the earthquake or its destructive power was similar to that which would be experienced by a building standing on a carriage which was suddenly caused to move with a velocity of about one foot and a half per second, or if, such a carriage having gradually acquired such a velocity, it had been suddenly arrested. The result of the earthquake was to overturn a few chimneys in Yokohama and to crack one or two in Tokio.

Our last severe earthquake was on February 22, 1880. On that occasion in Yokohama very many buildings lost their chimneys and were unroofed, whilst in Tokio the damage was chiefly confined to loosening tiles and shaking down plaster. Had our buildings in Japan been constructed like those in England, it is probable that this last shake would have caused about the same amount of damage as that which was so recently caused by the late disturbance in Essex. From the observations on direction, coupled with what has been said about time, it seems that the earthquake had its origin in Yedo Bay, at or about the same point as that which was determined for its severe predecessor.

It may here be remarked that nearly all the heavier earthquakes which are felt in Tokio and Yokohama practically have had a common centrum. They are not large earthquakes as measured by the area shaken, but they are severe because we are near to their origin.

The earthquake of 1880, according to a record furnished by one of Palmieri's instruments, had an intensity of 78°, whilst the recent earthquake, the actual intensity of which, as deduced by its destructive effect, was much less, is given as 95°.

These intensities measured in degrees really indicate the height to which a certain quantity of mercury in a bent tube was caused to wash—the height of the "wash" being measured by the turning of a pulley connected by a string to a small weight floating on the surface of the mercury. It would seem evident that the magnitude of the records obtained in this manner must among other things depend upon the duration of the earthquake, the period of its waves, and the depth of the mercury contained in the tube. For reasons such as these, records like those just given cannot be regarded as anything more than roughly approximative.

In connection with the remarks made on the amplitude it may be stated that the seismograph by which the record was taken was situated on soft soil in the flat portion of Tokio. This amplitude, had it been recorded on the hard ground of a hill, probably would not have exceeded 25 mm.

One of the most remarkable points connected with this disturbance were the changes in level as observed by the displacement of specially arranged pendulums, which took place before the shock, and again about six hours afterwards.

J. MILNE

Large Meteor

ONE of the largest meteors that I have seen for some years appeared at 7h. 15m. 15s. this evening. It began as a speck, north of Vega, at about 4° greater altitude than that star. The course was perpendicularly down, only disappearing by passing below the horizon. It was 2° east of Vega on descending to the altitude of that star, and by that time had increased to fully a quarter the apparent size of the moon, and this size it maintained whilst above the horizon. The colour was an intense blue, and there was left a streak of orange-red elongated separate stars in its track, and this streak was about 1° in length, although the separate stars of which it consisted disappeared almost as rapidly as they were formed. The stars, like the meteor, increased in size and brilliancy from a mere point, and instantly vanished on attaining their maximum brightness. Each moved perpendicularly down for the length of about half a degree, and left a continuous momentary streak. None of these stars were seen within half a degree of the meteor, and their ignition was confined to the centre of the meteor's path. Their size was tolerably equal, being about that of a second-magnitude star. The speed of the meteor was unusually slow, it being visible for nearly six seconds. The shape was circular in front and cuneate behind (bluntly conical). Its brilliancy was great, considering the presence of a nearly full moon.

The Cost of Anthropometric Measurements

ALLOW me to correct an absurd typographical blunder in the account of my anthropometric laboratory at the Healtheries, which appears in Mr. Ernest Hart's lecture at the Society of Arts. It originally occurred in the *Journal* of the Society of Arts, whence it was copied into your columns (p. 142) last week. The effect of the error to which I refer is to make the statement that the cost of measuring each person at the laboratory in seventeen different ways was *3l.*, whereas it should have been *3d.* The subsequent argument, based on the extreme cheapness of the process, becomes in consequence unintelligible. I write myself to make the correction, because the part of Mr. Ernest Hart's address which refers to the anthropometric laboratory was written for him, at his request, by myself. I regret I had not an opportunity of revising it in proof.

FRANCIS GALTON

The Northernmost Extremity of Europe

As "a Norwegian" now fully admits that the pretended discovery of Capt. Störensen is no discovery at all, but an elementary fact well known and long known to Norwegian geographers, I need not discuss that question any further, but I must protest against his reference to Sönsberg's "Norge," which is the joint production of some of the most eminent men in Norway. Sönsberg is the *editor* and *publisher*.

Amongst the writers who have co-operated to produce the national "Handbook" are the following:—Lieut.-Col. Broch, Chief of the Geographical Survey of Norway (he is the largest contributor, and the writer of the words I quoted), Prof. H. Mohn, Prof. T. Kjerulf, Prof. Rasch, Prof. L. K. Daa, Sorenskriver, H. Thoresen, J. B. Halvorsen (the well-known writer), Beaureauchef Kjer, and Secretary Mohn, Th. Bœck (Royal plenipotentiary), J. N. Prahm, Capt. Scharfenberg, E. Mohn, Lieut. Flood, Capt. Overgaard (the Inspector of Forests), Hörbye, Lieut. Langeberg, and Mr. Langeberg, K. Lassen, Dr. Kahrs, Lieut. Solem, O. T. Olsen, Capt. Bang, Capt. Haffner, and Sorenskriver Nannestad.

All these names are given in the preface, and the contributors of each carefully specified. This was known to "A Norwegian" when he wrote his last letter, for he refers to that same preface, and yet asserts that Sönsberg "never claimed the least *geographical* authority for a faulty and crude guide to tourists" (his own italics). That preface is written for the express purpose of claiming such authority and thanking the authors. It makes special claim in a special paragraph of the *geographical* authority of the "head of the Geographical Survey," Lieut.-Col. Broch, whose name, Sönsberg says, "offers a sufficient guarantee of correctness."

The anonymous "Norwegian," in further disparagement of the book, states that in this preface "the author himself says that for reasons explained it has many faults." I will quote this very damaging confession. It is as follows:—"A few errors and misprints will be found here and there." A list of them is given. After this the flippant misrepresentation of my pretensions in the last paragraph of the letter is not surprising, and demands no further notice.

I make this protest, knowing that NATURE is largely read by

well-educated Norwegians (who all read English as a matter of course). They cannot fail to be indignant if such unjust treatment of a national work, which genuine Norwegians understand and appreciate, is allowed to pass unrefuted. Besides which, Englishmen in search of available and reliable information concerning Norway might be grossly misled.

W. MATTIEU WILLIAMS

APOSPORY IN FERNS

A PARAGRAPH in the report in NATURE (p. 119) of the meeting of the Linnean Society for November 20 last contained what is, to the best of my belief, the first publication of one of the most interesting botanical observations which has been made for some time. As it is quite possible that this brief record may escape the notice of a good many botanists, I venture to give the matter a little more prominence.

At the meeting referred to, Mr. E. T. Druery made a second communication (the first did not, I think, receive any record) upon a singular mode of reproduction in *Athyrium Filix-fœmina*, var. *clarissima*. In this fern the sporangia do not follow their ordinary course of development, but, assuming a more vegetative character, develop more or less well-defined prothallia, which, according to Mr. Druery's observations, ultimately bear archegonia and antheridia. From these adventitious prothallia the production of seedling ferns of a new generation has been observed to take place in a perfectly normal way.

Mr. Druery very kindly offered at the meeting to supply me with some of his material. This reached me on November 29, and I immediately placed it in the hands of my friend Mr. F. O. Bower, who was engaged in other research connected with the vascular cryptogams in the Jodrell Laboratory of the Royal Gardens. Although in the material sent me the abnormal development of the sporangia had not proceeded very far, Mr. Bower obtained evidence which, as far as it went, was entirely confirmatory of the correctness of Mr. Druery's observations. With appropriate cultural treatment prothalliform bodies have already made their appearance, but have not yet reached the stage at which archegonia and antheridia are developed. They are, however, furnished with root-hairs.

This is, however, not all. Mr. Bower placed himself in communication with Mr. Druery, and paid a visit to his collection of ferns. By the kindness of this gentleman he was allowed to bring away specimens of another fern (*Polystichum angulare*, var. *pulcherrima*) which altogether eclipses the *Athyrium*, remarkable as that is. In the *Polystichum* the apex of the pinnules grows out into an irregular prothallium, upon which Mr. Bower with little difficulty was able to demonstrate at Kew the existence of characteristic archegonia and antheridia. In this case the production of the prothallium is not even associated locally with the sporangia, but it appears as a direct vegetative outgrowth of the normal spore-bearing plant. The oophore is a mere vegetative process of the sporophore, a suppression of the alternation of the two generations which exceeds even that which obtains in the flowering plant.

Mr. Druery's discovery, for which I have borrowed Mr. Bower's convenient term Apospory, is the direct converse of the Apogamy in the fern, discovered by Prof. Farlow. In this the sporophore is a vegetative outgrowth from the oophore. The parallel phenomena in the life-history of the moss have been known for some time. But this point and all detailed observations at present available will be dealt with in the communication which Mr. Bower will make at the meeting of the Linnean Society this (Thursday) evening. While every merit must be attributed to Mr. Druery for the first observations of this important fact, he has with great liberality allowed Mr. Bower free liberty to discuss the histological and theoretical points involved.

The obvious possibilities of discovery with regard to the reproduction of ferns may now be regarded as exhausted. It may be interesting to give the dates of the different steps:—

1597	Gerarde	Observed seedling plants near parents.
1648	Cæsius	Sporangia.
1669	Cole	Spores.
1686	Ray	Hygroscopic movements of sporangia.
1715	Morison	Raised seedlings from spores.
1788	Ehrhart	Prothallium.
1789	Lindsay ...	Germination of spores.
1827	Kaulfuss	Development of prothallium.
1844	Nägeli	Antheridia.
1846	Suminski	Archegonia.
1874	Farlow	Apogamy.
1884	Druery	Apospory.

Royal Gardens, Kew W. T. THISELTON DYER

MODERN ENGLISH MATHEMATICS[1]

YOU will remember that two years ago it was announced from this chair that the Council had settled the conditions under which the De Morgan Medal should be given, and that the first award would be made at the anniversary meeting of 1884.

I have now to make the announcement that the Council has decided that the first medal should be given to Prof. Cayley, in acknowledgment of his work in the theory of invariants.

As this is the first award of the medal, I may remind you of its origin. Soon after the death of De Morgan, some of his admirers started a subscription for the double purpose of having a bust executed and founding a medal to be given in his memory. The *bust* now adorns the library of the London University, where also his valuable collection of books is preserved. The *medal* was offered to the Mathematical Society, and its Council accepted the honourable duty of determining its award. There is a peculiar fitness in the medal being thus connected with our Society; for this Society was founded with the active co-operation of De Morgan by a number of his advanced students, among whom his talented son George, who died soon afterwards, took the lead. De Morgan himself was the first President, and our *Proceedings* begin with a very characteristic opening speech by him.

The medal is to be given for eminent original work in mathematics, and no more fitting memorial than this could in my opinion be devised for a man who spent his whole life in carefully preparing the foundation for such work by his teaching and his writings.

De Morgan was pre-eminently a teacher. His most original work does not so much increase our stock of mathematical knowledge, but is concerned with mathematical reasoning, and with exact reasoning in general.

In the opening speech referred to, De Morgan himself divides exact science into two branches, *the analysis of the necessary laws of thought*, and *the analysis of the necessary matter of thought*. His own work belongs to the former. He was a logician much more than a mathematician in the ordinary sense of the word, and when reading his mathematical works I have always had the feeling that he studied mathematics not so much for its own sake as on account of the logic contained and exemplified in it. I once made this remark in the Professors' Common Room of University College, when an old colleague of his turned round and said, "You are quite right, he told me so himself."

In this work De Morgan did not stand alone. We may almost take him as a type of his period. It has often struck me as a noteworthy fact that in England, after the long pause in mathematical activity, the work taken first in hand was investigation into the very bases

[1] An address delivered by Prof. Henrici, F.R.S., at the annual meeting of the London Mathematical Society (November 13), on the occasion of presenting the De Morgan Memorial Medal to Prof. Cayley, F.R.S.

of mathematics and more particularly into mathematical reasoning. These investigations became partly a mathematical analysis of logic itself and partly a logical analysis of the laws followed by the symbols and operations used in mathematics. De Morgan worked in both directions; we have his "Formal Logic" and his "Double Algebra." Operations were studied quite independently of the meaning given to the symbols. Originally the symbols stood for concrete things, and each operation had its concrete meaning. At present symbols are sometimes used without giving them any meaning whatsoever, and without defining them at all, and then the operations for combining these symbols are arbitrarily defined, with the sole restriction that they do not contradict each other.

Each new set of operations thus establishes a calculus. If afterwards any entities can be found which can be combined by operations answering the characteristics of the operations used in the new calculus, then the latter may be employed for a theory of those entities, and its results will allow of an interpretation. These entities themselves may be anything, concrete things, or logical concepts, or ordinary algebraical quantities.

Thus the ground was already prepared for greatly extending the realm of algebra and the scope and power of algebraical operations, when the genius of Prof. Cayley conceived the idea of invariants [1] which has given rise to that marvellous growth of our science which has suddenly brought England again far to the front.

It was known from Gauss's investigations that for quadratic expressions a certain combination of its constants, its determinant, exists, which has the following property.

If the quadratic expression be transformed into another by a linear substitution, then the determinant of the transformed expression is obtained from that of the original expression by multiplying it by a factor which depends solely on the substitution used.

Afterwards Eisenstein discovered that a similar theorem holds for a cubic expression of one variable. These isolated facts suggested to Cayley that combinations of constants having this property must exist for all algebraical expressions. The problem was how to find these.

The manner in which this has been solved I need not restate here, but I wish to call your attention to the fact that the symbolic methods worked out by the school of mathematicians referred to have been of the greatest use in the development of the theory of invariants, which could scarcely have been brought to its present perfection without it.

It would be an impertinence for me to say much either in praise of Prof. Cayley's work or in justification of the Council's choice. Prof. Cayley has invented and worked out the theory of invariants, and in steady life-long work connected it with nearly every branch of mathematics, enriching everything he touches, and everywhere throwing open new vistas of future work.

The Council of the Mathematical Society in selecting Prof. Cayley as the first recipient of the De Morgan Medal, and thus doing homage to his genius, did so not so much with the idea that it could add honour to his name as that they might add honour to the medal by connecting his great name with it, and thus increase its value for all future recipients. And it is befitting that a body like the London Mathematical Society should give formal expression to the reverence and admiration in which it holds the greatest among its members.

[1] Prof. Cayley, when returning thanks, distinctly waived the claim of priority in favour of the late Prof. Boole. See also Salmon's "Higher Algebra," p. 294.

PHYSICAL GEOGRAPHY OF THE MALAYAN PENINSULA

AS some remarks of mine on the mountain system of the Malayan peninsula have already appeared in NATURE, perhaps the following summary of the results of ten months' explorations in the State of Perak will be interesting.

The State of Perak is comprised between the sea (Straits of Malacca) and the main central chain which runs along the centre of the peninsula. Its boundaries are, roughly: north, the River Krian; south, River Bernam; west, the ocean; east, the main central chain. The geology may be briefly described as consisting of—

(1) An immense granite formation, rising into extremely sharp and precipitous parallel ridges having nearly a meridional direction. This granite passes frequently into slates and schists. The prevailing colour is blue.

(2) A Palæozoic formation of slates, mottled sandstones, and clays, forming outliers or detached portions. It is found most abundantly at the foot of the ranges, whence it usually dips away conformably to the slopes of the hills and mountains. It has evidently been subject to great denudation.

(3) Limestone in detached outliers, or isolated hills of precipitous character, showing much denudation. It is stratified or crystalline. No fossils have been found yet, but is probably of Palæozoic age. From its wide extension throughout Perak, where it crops out in so many places, it may have once covered the whole of the granite and Palæozoic clays.

(4) Drifts and alluvium from the ancient streams and river beds. These are formed of the material from all the preceding deposits. All the tin deposits of the country are in these drifts. The ore occurs in a manner very similar to the alluvial gold in Australia, that is to say, in "leads," which are the ancient or modern river beds.

Above these alluvial deposits there is the usual alluvial surface soil, for the most part supporting a very dense vegetation.

The tin deposits hitherto found are all stream tin. No lodes have yet been worked, though there are some in the mountains round the sources of the Perak River. The ore is almost always cassiterite in small abraded crystals. It is of a peculiar blackish-gray or brown aspect. Any person with a little experience would be able to distinguish between tin sand from Australia and that of Perak. The former is rather rich in gems, such as sapphires, rubies, hyacinths, garnets, topazes, and zircons. I have never seen any in Perak; but there is a good deal of fluor-spar, tourmaline, and less frequently wolfram.

The most of the workings are on the western slopes at the foot of the mountains. I cannot recall any instances of mines on the eastern slopes, but the wash or drift seems to have been greater on that side.

The matrix of the tin seems to be in the upper part of the granite at its junction with the Palæozoic clays. In the lower part of the clay there is also a small quantity of tin.

In the drift the tin is always found in nearly the lowest levels, lying in one or two strata from one foot to five feet thick. It is mingled with fine drift sand and gravel. Its position is, I think, due to the repeated sifting and washing it has been subject to in the stream bed. But as it is generally covered by from ten to thirty feet of material destitute of tin, the inference is that only one part of the granite was very rich in the metal.

The stream tin deposits lie upon (1) kaolin clay, or partly decomposed granite; (2) granite; (3) Palæozoic sandstones and clays. In the latter case the stream has come from the denudation of a portion of the same strata on the upper slopes of the hills.

On the highest granite ridges, or those above 5000 feet, there is found a distinct vegetation. Three or four of the genera are Australian (*Melaleuca*, *Leptospermum*, *Podocarpus*, *Leucopogon*), and two of the species (*Leptospermum* and *Leucopogon*) are common Australian forms. Similar facts have been observed in Borneo, but I have

not heard that they had been observed in the Malay peninsula. Nothing of the kind is seen on the lower slopes of these mountains even 100 feet below the summit. This Australian flora may be the relics of an ancient flora, which once included the Eastern Archipelago. But it does not appear why the species should be confined to the tops of the mountains. They grow in a much warmer climate in Australia.

There are no table-lands in Perak; the mountains are all sharp ridges. There is not the slightest sign of any recent upheaval of the coast-line, while the evidence of subsidence is equally absent. But the land is rapidly encroaching on the sea owing to the immense alluvial wash brought daily from the mountains in this land of heavy rains. Thus the shores are fringed with large mangrove swamps which yearly extend, and the Straits of Malacca form a shallow sea full of mud banks and shoals. The seas are consequently rather poor in certain forms of marine life to which muddy sediment is unfavourable.

Though the tin has been worked for centuries, only a comparatively small portion of the country has been worked out or worked at all. I consider that the deposits in Perak are practically inexhaustible. The mining industry is almost exclusively in the hands of the Chinese, who are almost the perfection of colonists for a country like this. Malays are not good miners. Gold is found associated with tin, but small, scaly, in sparing quantity, and only in one or two places.

There are only two instances known to me of the occurrence of recent volcanic rocks: one is in the Kinta River valley, the other on the western face of a small group of mountains not far to the east-south-east of the island of Penang, and near the Karau River. The rocks appear to be basaltic dykes, but the thick jungle and surface weathering prevented a proper examination.

The mountain system of this native State consists of detached groups of mountains which cover the west side of this part of the peninsula, an almost continuous range close to the sea in the Straits of Malacca. These groups of mountains form parallel chains about thirty miles long, with a direction a little oblique to the true meridional line. Sometimes they are wholly detached groups, so as to allow rivers from the eastward to pass between them. Such an instance is seen in the ranges between the Kinta and Perak rivers. This group terminates to the north so as to allow the River Plus to pass to the westward and to the south so as to give an outlet to the Kinta. Both rivers join the Perak River, which flows round another group (Gunong Bubu), and then flows into the sea in the Straits of Malacca.

The islands of the coast, such as the Dindings and those off the State of Keddah (Pulo Leddas, Pulo Lankawi, and Pulo Buton, known as the Buntings), are probably portions of similar groups, and so are Pulo Penang and the attendant islands. These groups and those on the mainland usually run in sharp parallel ridges, variously modified by oblique spurs, which at times connect the main chains forming watersheds which throw off small streams north-east and south-west.

The following are the principal groups of mountains known to me, beginning at the south:—

Dindings Islands.—Off the coast in front of the Dindings River (*Dinding*, Malay for boundary or partition), lat. 4° 12′ N., there is a series of islands of moderate elevation not exceeding 1000 feet in their highest peaks. They are granite, rich in tin, with a little fine scaly gold. They are densely clothed with jungle, and have fringing reefs of coral. I have visited three or four of these islands, and they are all of the same character.

On the mainland there is a cluster of hills called the False Dindings, from the fact that at a short distance they look like islands. These are also granitic, and tin occurs in the alluvial beds derived from them. They give rise to small rivers, such as the Dindings and its tributaries.

Gunong Bubu.—North-east of this group, but quite detached from it, is a series of parallel mountain ridges with a uniform trend of north-north-east. These ridges are eight or nine in number. The central one is the highest, culminating in Mount Bubu, a fine peak of about 5600 feet elevation. All the ridges are granitic, with occasional patches of metamorphic schists, all more or less rich in tin. A remarkable character in this range is that all the ridges are extremely steep, and frequently interrupted by granite precipices of 1000 feet and more. Gunong Bubu is only accessible in one or two places, the summit being surrounded by escarpments of rock of great height.

Many small streams join the Perak River and the sea from this range. The Kaugsa and Kenas both flow into the Perak to the eastward. In an ascent made by me to the summit of Mount Bubu I was able to explore some of the sources of both these rivers, which afford a home to many a rhinoceros, but few other animals except monkeys (*Hylobates*, *Semnopithecus*, and *Macacus*). The rivers descend many hundred feet in a series of cascades, giving rise to some of the finest scenery in the Malay peninsula.

North of Mount Bubu this group of ridges falls away abruptly, leaving a narrow pass (Gapis Pass) between them and the next group. This pass is about 400 feet above the level of the sea, and therefore too elevated to permit of any river outlet.

Mount Poudok.—In Gapis Pass, or rather at the eastern end of it, there is an isolated hill of highly crystalline limestone. It is an outlier of the great Palæozoic limestone formation already referred to. It is about 400 feet high, and quite precipitous. Its junction with the granite or Palæozoic clays is not visible. Its bright blue and red precipices crowned with dark-green jungle make it a singular and beautiful object, but there are many similar in the State.

Mount Ijau.—North of Gapis another group of ranges succeeds, culminating in Mount Ijau (Malay for green) at about 4400 feet above the sea. This cluster of ridges appears to me to be of nearly the same dimensions as the Mount Bubu group, but not so high by 1000 feet or so. I estimate that each group is from twenty to twenty-five miles long, and fourteen to sixteen broad, covering an area of about 400 square miles. This, however, is only a rough estimate formed from views I have been able to obtain from the summits of other mountains. I have not been able to examine personally the termination of the Mount Ijau group on the north. From the sea one is able to perceive a distinct pass like that of Gapis. It is probably about the same height, and does not form the outlet of any river from the eastern side.

Kurau Group.—North of Gunong Ijau is another group, which I do not know how to distinguish except that it forms the watershed of the Kurau River. Its highest point is a mountain which is also called Ijau by the Malays. I have not ascended the peak, but it seemed to me less elevated than Mount Ijau to the south.

Mount Inas.—What the Malays of Keddah call Mount Inas is the highest point of another detached group north of the Krian and Selama Rivers. I have been within a few miles of the foot of this mountain, and it seemed to me to be somewhat over 4000 feet high, and the highest point of an isolated group of ridges.

Keddah Peak.—North of Mount Inas, in the State of Keddah, there is, close to the sea, a detached group of mountains, at the foot of which the Keddah River flows. Keddah Peak is the highest summit,—probably over 4000 feet high. This is in what is called Lower Siam, in which I have only travelled to a very trifling extent north of the Krian River, the boundary of Perak State. In the north of Perak, near Patani, we have other groups of mountains. An Italian explorer named Bozzolo, who

has lived many years in Siam, assures me that he has travelled round the Gunong Kendrong group at the head of the Perak, and that it is quite detached from any other hills.

Perak River.—The whole of these groups are sufficiently connected to prevent any drainage from the central range flowing directly to the west coast of the peninsula. Thus the Perak River, which has its sources in the Keddah and Patani Mountains flows to the southward for over 180 miles. In its course it is joined by two important rivers from the eastward, namely, the Plus and Kinta.

Plus River.—The Plus River has its sources in the high mountain groups east of Mount Inas, and in the main range. It flows round the southern end of a group called by some the Bukit Panjang Range, and then joins the Perak.

Kinta Ranges.—South of this junction is a group of mountains called by some the Kinta Ranges. This group is about twenty-five miles long. It is perfectly detached from all the others, having a generally north and south direction, but sending off spurs from its west side a little to the west of south. The group is entirely granitic, but on its lower slopes has thick deposits of limestone belonging to the formation already referred to, above and below which tin is worked. For about twenty-five miles this range separates the valley of the Perak River from that of the Kinta, which flows on its eastern side. The highest peaks rise to about 3750 feet above the sea, and give rise to small streams which all flow into the Perak. There is a remarkable uniformity in three or four of the highest summits, which are about the centre of the chain, Mounts Merah (red), Prungin, &c. They are all within a few feet of the same height. From these mountains the range falls away gradually to the south, and sends off two considerable spurs to the south-west. Where it ceases the River Kinta joins the Perak.

Kinta Valley.—The valley of the Kinta River is about as wide as that of the Perak. The river flows, like the Perak, on the eastern side of the valley. The eastern tributaries are many and important. On the sides limestone granite and schistose slates crop out. To the eastward there are many detached hills of limestone fronting the main central chain. They form very characteristic features in the landscape, from their precipitous outline, and the brilliantly coloured faces of blue, green, and bright red rock. They are also distinguished by a different vegetation.

Perak Valley.—The valley of the Perak River is bounded by the groups of mountains already described on the west; on the east by the Kinta Range, and north of the Plus by the Bukit Panjang Range. The river flows on the eastern side of the valley; this is owing to the many spurs and outliers on the eastern sides of Mounts Bubu and the Ijau Ranges. It seems as if there had been much less denudation on the eastern than on the western sides of the range. This may be owing to the prevailing rains falling more abundantly on the western than on the eastern sides of the mountains.

As a consequence of this the tin workings appear to be, with little exception, on the western sides of the ranges, where the waste and wash has probably been greater.

Batu Kurau.—Between Mount Bubu Range and Mount Ijau Range and the sea there are no hills except small outliers, mostly of Palæozoic clay, which have evidently belonged to the ranges. But north of the Larut River there is an isolated limestone mountain near the Kurau River. This is called Batu (stone or rock in Malay) Kurau. It is very similar to Mount Poudok in the Gapis Pass. It is quite unconnected with the main range, and rises out of the plain between the spurs which form the valley of the Kurau River. There is also a small detached range dividing the valley of the Krian River from that of the Kurau.

Main Range.—Of the main range I know but very little from personal observation, having only visited it at Goping, and at the limestone hills, where the tin is worked on the Diepang River. But I have travelled along the most of the Kinta Valley skirting the base of the range either on foot or in boats. I have also traced the valley of the Kampar River. The geology is like the rest of the country, mainly granite, slates, and limestone, with traces of basaltic rocks. The general structure of the range can best be judged from some of the mountains to the westward. It forms a most imposing boundary to the whole of the western horizon. In the north, about the sources of the Plus River, there is a mountain of rounded outline, probably over 6000 feet high. The range there declines a little, with a somewhat serrated outline, but generally over 3000 feet. At a point corresponding with the latitude of about the centre of the Kinta Range, or opposite the Gapis Pass, the chain increases in elevation to perhaps over 5000 feet, and in the distance is seen a peak which must be over 8000 feet high. I know no name for this hill, but it is the most distant mountain usually seen. South and west of this the chain rises into a grand cluster of peaks, the highest of which is over 7000 feet. This is Gunong Robinson. It looks higher than the Sugar-Loaf Hill as seen from Gunong Bubu, but then it is much nearer. From Gunong Robinson the range declines to the southward, but is still a bold series of picturesque peaks, many of which must be over 6000 feet. It has been asserted by more than one observer that to the south of the point where the range is lost sight of from Arung Pura, there is a high mountain occasionally visible higher than any other in the main range, and probably over 12,000 feet. This I have not seen, but I am convinced that there are many things yet to be learned about the most elevated portions of this mountain chain. Seen from any point of view, it forms a magnificent mountain prospect. Its mysterious unexplored recesses are rendered more gloomy than any scene in the world from the dense forest and the masses of vapour and cloud with which they are always clothed. A few savage Sakies are the only inhabitants. I may add that perhaps in no country in the world is exploration rendered so difficult from the extraordinary thickness of the jungle and the steepness of the mountain ridges which unceasingly cross the traveller's path.

Penang, September 8 J. E. TENISON-WOODS

A NEW APPLICATION OF SCIENCE

DR. FERRIER'S researches on the brain, to which we have often drawn attention in these columns, have lately received an application of the most startling character. What this application is cannot be better stated now than in the accompanying letter, signed "F.R.S.," which appeared in Tuesday's *Times*. We shall return to this subject next week.

"While the Bishop of Oxford and Prof. Ruskin were, on somewhat intangible grounds, denouncing vivisection at Oxford last Tuesday afternoon, there sat at one of the windows of the Hospital for Epilepsy and Paralysis, in Regent's Park, in an invalid chair, propped up with pillows, pale and careworn, but with a hopeful smile on his face, a man who could have spoken a really pertinent word upon the subject, and told the right rev. prelate and the great art critic that he owed his life, and his wife and children their rescue from bereavement and penury, to some of these experiments on living animals which they so roundly condemned. The case of this man has been watched with intense interest by the medical profession, for it is of an unique description, and inaugurates a new era in cerebral surgery; and now that it has been brought to a successful issue, it seems desirable that a brief outline of it should be placed before the general public, because it illustrates vividly the benefits that physiological explorations may confer on mankind, shows how speedily useful fruit may be gathered from researches undertaken in the pursuit of knowledge and with no immediate practical aim, and reveals

impressively the precision and veracity of modern medical science.

"This case, then—this impressive and illustrative case—is that of a man who, when admitted to the Hospital for Epilepsy and Paralysis, presented a group of symptoms which pointed to tumour of the brain—a distressing and hitherto necessarily fatal malady, for the diagnosis or recognition of which we are indebted to bed-side experience and post-mortem examination. But while clinical and pathological observations have supplied us with knowledge which enables us to detect the existence of tumours of the brain, they have not afforded us any clue to the situation of these morbid growths in the brain mass, and it was not until Prof. Ferrier had, by his experiments on animals, demonstrated the localisation of sensory and motor functions in the cerebral hemispheres that the position of any diseased process by which they might be invaded could be definitely determined. By the light of these experiments it is now possible in many instances to map out the seat of certain pathological changes in these hemispheres with as much nicety and certainty as if the skull and its coverings and linings had become transparent, so that the surface of the brain was exposed to direct inspection. And thus in the case to which I am referring, Dr. Hughes Bennett, under whose care the patient was, guided by Ferrier's experiments, skilfully interpreted the palsies and convulsive movements which the man exhibited, and deduced from them that a small tumour was lodged at one particular point in his "dome of thought," and was silently and relentlessly eating its way into surrounding textures. Not more surely do the fidgetings of the electric needle intimate their origin and convey a meaning to the telegraph clerk than did the twitchings of this man's muscles announce to Dr. Hughes Bennett that a tumour of limited dimensions was ensconced at a particular point of a particular fold or convolution of the brain—the ascending frontal convolution on the right side.

"Very brilliant diagnosis this, it may be remarked, and nothing more. A conclusion has been arrived at which, should it prove correct, will gratify professional pride; but as it cannot be confirmed or refuted until the poor patient is no longer interested in the matter, and cannot be made the basis of any active interference, no great advance has been made after all, and vivisection has yielded only some barren knowledge. Until quite recently, criticism of this kind would have been justifiable in a sense, but now it is happily no longer possible, for another series of experiments on living animals, undertaken by Profs. Ferrier and Yeo, have proved that through our power of localising brain lesions we may open a gateway for their removal or relief. The old notion that the brain is an inviolable organ with *noli me tangere* for its motto—a mysterious and secluded oracle of God that simply falls down and dies when its fane is desecrated by intrusion—has been dissipated by these experiments; and we now know that under punctilious antiseptic precautions the brain, in the lower animals at any rate, may be submitted to various operative procedures without risk to life or fear of permanent injury. Emboldened by this knowledge, Dr. Hughes Bennett devised a way of helping his patient whose disease he had diagnosed with such remarkable exactitude, and gave him one chance, if he had the courage to embrace it, of saving his life and recovering his health.

"The patient had the position in which he stood faithfully explained to him. He was told that he laboured under a malady which medicines were powerless to touch, and that if left unassisted he must die in a few months at latest, after prolonged sufferings similar to those which had already brought him to the verge of exhaustion, and which could be only partially alleviated by drugs; but that one outlet of escape, narrow and dangerous, but still an outlet, was open to him in an operation of a formidable nature and never before performed on a human being, under which he might, perhaps, sink and die, but from which he might, perhaps, obtain complete relief. The man, who had faith in his doctor, and no fine-spun scruples about availing himself of the results of vivisectional discoveries, eagerly chose the operation. On the 25th ult. accordingly, Mr. Godlee, surgeon to University College Hospital, in the midst of an earnest and anxious band of medical men, made an opening in the scalp, skull, and brain membranes of this man at the point where Dr. Hughes Bennett had placed his divining finger, the point corresponding with the convolution where he declared the peccant body to be, and where sure enough it was discovered. In the substance of the brain, exactly where Dr. Hughes Bennett had predicted, a tumour, the size of a walnut was found—a tumour which Mr. Godlee removed without difficulty. The man is now convalescent, having never had a bad symptom, and full of gratitude for the relief afforded him. He has been snatched from the grave and from much suffering, and there is a good prospect that he will be restored to a life of comfort and usefulness. In that case he will be a living monument of the value of vivisection. The medical profession will declare with one voice that he owes his life to Ferrier's experiments, without which it would have been impossible to localise his malady or attempt its removal, and that his case opens up new and far-reaching vistas of hopefulness in brain-surgery. Many men and women will henceforth, there is reason to anticipate, be saved from prolonged torture and death by a kind of treatment that has been made practicable by the sacrifice, under anæsthetics, of a few rabbits and monkeys."

NOTES

The Council of the British Association for the Advancement of Science has requested the following to allow themselves to be nominated as Presidents of Sections for the meeting at Aberdeen, which begins on Wednesday, September 9, 1885:—Section A (Mathematics, &c.), Prof. J. C. Adams; Section B (Chemistry), Prof. Armstrong; Section C (Geology), Prof. Judd; Section D (Biology), Prof. McIntosh; Section E (Geography), General Walker; Section F (Economics), Prof. J. Bryce; Section G (Mechanics), Mr. B. Baker; Section H (Anthropology), Mr. F. Galton.

We learn with pleasure that M. Mascart was on Monday last elected a Member of the Academie des Sciences, Paris.

The Berkeley Research Fellowship has been given by Owens College, Manchester, to Mr. G. H. Fowler of Keble College, Oxford. An opportunity is thus given to Mr. Fowler of carrying on his work on the anatomy of the Zoantharian corals.

The immense economical importance of Government botanic gardens, especially in young colonies, is well shown by the last report of the Curator of the Gardens in Brisbane. Omitting the distribution of ornamental trees, shrubs, &c., to the gardens of public institutions, as well as that of ornamental pot plants, we find that economic plants have been distributed on a very large scale. The demand for these has been unprecedentedly large, and no application is ever refused so far as it can be supplied. About 3000 economic plants were sent out during the year; these consisted chiefly of various kinds of coffee, tea, cocoa (*Theobroma cacao*), cinchona, and vanilla. Grafted Indian mangoes and plants of the Brazilian nut (*Bertholletia excelsa*) have been given to likely growers, and the demand for the latter is so great that application has been made to the universal feeder of these institutions, Kew, for more. Besides acting as a collecting and distributing agency, the Brisbane Gardens do what is perhaps of even more value, viz. ascertain by experiment the conditions under which certain foreign plants will grow best in the colony. The most important trials recently have been with regard to cinchona, which, Mr. Pink shows, may by care in its early stages, be successfully cultivated in Queensland. The hop plant has been tried, and appears a success, 10 cwt. being the produce per acre the first season, while in England under similar circumstances it is only 4 cwt. Sugar is at present the staple of the colony, but no efforts are spared to discover new kinds elsewhere which may be better adapted to the place. 100 tons of various kinds of cane, chiefly from Mauritius, were sent to planters during the year. Economic and valuable timbers also receive much attention, and the gardens have now ready for transplanting 20,000 trees of various kinds, including cedars, olives, silky oak, English oak, English ash, poplars, and chestnuts. The recent experiments have conclusively shown that Queensland can introduce among her staple produce-crops such valuable and remunerative products of the soil as coffee, hops,

and cinchona. As an example of the care and labour devoted to the work, it may be mentioned that every method of cultivating the cinchona in Ceylon and South America was tried in the gardens without much success; and finally Mr. Pink was compelled to devise a method of his own, which proved successful.

We regret to announce the death of Dr. Heinrich Bodinus, for many years Director of the Berlin Zoological Gardens; he died at Berlin on November 23 last. Also of Dr. Karl von Vierordt, formerly Professor of Physiology at Tübingen University; he died at that place on November 22, aged sixty-seven.

La Nature records the death of M. Henri Lortigue, to whom is due the practical introduction of the telephone in most of the large towns in France, and who was in many other respects a man of scientific note. In 1855 he was employed by Leverrier, the Director of the Paris Observatory, who was then organising a series of meteorological observations, to superintend the instruments by which, by means of photography and electricity, the slightest variations of the barometer, thermometer, and compass were recorded. In 1859 M. Lortigue took charge of the telegraph service on the Chemin de Fer du Nord, and received a gold medal for his various inventions of semaphores, automatic whistles, &c. In 1880 he was Director of the Société des Téléphones. He was also a botanist and entomologist of note, and has left behind him some excellent collections in natural history.

The part of Turkestan bordering on China and comprising the countries retroceded by Russia, is now entirely incorporated with the Chinese Empire, and will form henceforward the 19th Province.

We have received from Messrs. Collins of Glasgow the new edition (twentieth thousand) of Prof. Guthrie's well-known "Text-Book of Magnetism and Electricity." Not only has the present edition been carefully revised, but it contains a supplementary chapter by Mr. C. V. Boys, referring chiefly to the practical applications which have been made of electricity during the last few years, such as the telephone and microphone, dynamo machines, electric light, secondary batteries, &c. Electric and magnetic units are also referred to at some length.

Our readers will be glad to know that the Fine Art Society announces the publication of an etching of Prof. T. H. Huxley, after the picture painted by Mr. John Collier, which was exhibited at the Royal Academy in 1883. The etching is the work of the distinguished etcher, M. Léopold Flameng, and corresponds in size with the portrait of the late Mr. Charles Darwin, painted and etched by the same artists, and published by the same Society last year.

An examination of a series of water-marks set in 1750 all round the Swedish coasts, from the mouth of the Tornea to the Naze, in order to settle a dispute between the Swedish astronomer Celsius and some Germans, as to whether the level of the Baltic has been rising or sinking, shows that both parties were right. The gauges were renewed in 1851, and again this year, and have been inspected regularly at short intervals, the observations being carefully recorded. It appears that the Swedish coast has been steadily rising, while that on the southern fringe of the Baltic has been as steadily falling. The dividing line, along which no change is perceptible, passes from Sweden to the Schleswig-Holstein coast, over Bornholm and Laland. The results have lately been published by the Swedish Academy of Sciences; and it appears from them that while during this period of 134 years the northern part of Sweden has risen about 7 feet, the rate of elevation gradually declines as we go southwards, being only about 1 foot at the Naze, and nothing at Bornholm, which remains at the same level as in the middle of the last century. The general average result would be that the Swedish coast has risen about 56 inches during the last 134 years.

The Central Geodynamic Observatory at Rome recently received notice from Corleone, in the province of Palermo, of another violent shock of earthquake, making the fourth in Italy in less than a fortnight. The first occurred on November 23, at 7.30 p.m., on the eastern slope of the Western Alps, and coincided with the reawakening of Vesuvius. The second, at midnight on the 27th, extended from the same region to Switzerland and Lyms on the north, and to the Liguarian coast of Italy. The third, at midnight on the 29th, shook Cosenza and Paola in Calabria. The fourth touched Sicily at Corleone at four o'clock in the afternoon of the 5th inst. During this period an unusual agitation had been noted in the seismographic instruments at Rome and elsewhere in Italy. Prof. Di Rossi, Director of the Geodynamic Observatory, announces the early publication of very interesting observations taken at Rocca di Papa, comprising the alterations in level, and in the temperature of subterranean waters.

A notice has just been received from M. Hepites, who has long been carrying on meteorological observations in Roumania, to the effect that the Roumanian Government has decided on the establishment of a meteorological organisation, and has voted the necessary funds. The Central Institute is being built at Bucharest. The organisation was started July 1. M. Hepites is the director.

In a paper recently read before the Shanghai branch of the Royal Asiatic Society, Dr. Macgowan affirms the claims of the Chinese to be the originators of gunpowder and firearms. This claim was examined in an elaborate paper some years ago by the late Mr. Mayers, and decided by him in the negative. Dr. Macgowan admits that gunpowder as now used is a European discovery. Anterior to its granulation by Schwartz it was a crude compound, of little use in propelling missiles; this, says the writer, is the article first used in China. The incendiary materials stated by a Greek historian to have been employed by the Hindus against Alexander's army, are stated to have been merely the naphthous or petroleum mixtures of the ancient Coreans, and in early times used by the Chinese. The "stink-pots," so much used by Chinese pirates, is, it appears, a Cambodian invention. Dr. Macgowan states also that as early as the twelfth or thirteenth century the Chinese attempted submarine warfare, contriving rude torpedoes for that purpose. In the year 1000 an inventor exhibited to the then Emperor of China "a fire-gun and a fire-bomb." He says that while the Chinese discovered the explosive nature of nitre, sulphur, and charcoal in combination, they were laggards in its application, from inability to perfect its manufacture, so, in the use of firearms, failing to prosecute experiment, they are found behind in the matter of scientific gunnery.

In *The Hull Quarterly and East Riding Portfolio*, edited by W. G. B. Page, Sub-Librarian of Subscription Library, Hull, will appear, during the year 1885, interesting articles by T. M. Evans, President of the Literary and Philosophical Society, Hull, on the ancient Britons and the lake-dwelling at Ulrome in Holderness; A. C. Hurtzig, C.E., on some tidal and engineering features of the River Humber: and William Lawton, on the meteorology of Hull.

The Leicester "Literary and Philosophical," now entering upon its jubilee year, appears to be a flourishing society in a flourishing town. Over 300 members distribute themselves into five sections, containing many ladies as Associates, and both making outdoor excursions for practical observation, and holding evening meetings at which lectures are given, professional as well as amateur, followed at the latter by discussions. These lead to the collection and distribution of valuable knowledge of archæology, literature, and economics; of astronomy, physics,

and chemistry; of geology, where the exposures made by local railway cuttings are carefully studied and recorded; of biology (combining botany and zoology); and of zoology, specially directed to the study of the animals of the county, a list of which will be published as it approaches completeness. Some of these productions are not among the abstracts at the end of the Report, being reserved for publication in "another place." These papers are read in a new lecture-hall adjoining the Museum, another institution which, though not very extensive, is in a most active state of growth and improvement. A new curator has led to a thorough rearrangement of the zoological collection in such cases and surroundings as show the specimens in their natural habitats, with index sketches attached to each case, supplying names, &c., hanging near. So large an outlay has been made upon these cases, that only 4 per cent. of the expenditure has been devoted to fresh objects. A large increase in the number of visitors has followed these reforms, and nothing, we venture to say, would so increase the attendance at a museum as the introduction of variation instead of rigid order, and the contributions from South Kensington can best assist in this "movement." It seems hardly possible than an institution like this should be frequented by persons engaged in business when the hours of opening it are only the middle hours of the business day, viz. from ten till four, and the fact that on a holiday like Whitsun Monday 97 persons per hour were admitted during the daytime, and 353 persons per hour were admitted in the evening, shows that, here at any rate, the latter hours are the favourite hours also. Why, on the same ground, should a series of "popular" lecturettes be given at three o'clock in the afternoon?

Dr. A. Penck has recently studied the old glaciers of the Pyrenees in detail, and has found remarkable differences between them and the Alpine glaciers of the Ice period. Even at that remote period the Pyrenean glaciers were of far smaller extent than those of the Alps—in the western part of the Pyrenees indeed there existed not a single one. Wherever traces of glaciers could be found they were accompanied by lake beds; these have by now been filled up for the greatest part, at least in the lower altitudes, the only lakes still existing being situated in altitudes of between 1500 and 3000 metres.

We have received a pamphlet on the climatic conditions of Luxor and Egypt, with especial reference to invalids, by Dr. Maclean (H. K. Lewis). The author spent three years as an invalid and also in the practice of his profession in Egypt. There are several meteorological tables and diagrams, and very much information of all kinds for the traveller, although the traveller who wants to escape the English winter is the special object of the writer's solicitude.

Prof. Lindström, the keeper of the palæontological collections at the Stockholm Museum, has made an interesting discovery amongst a number of petrefacts obtained from the Island of Gothland. It is an air-breathing crustacean from the Silurian period, the first specimen of the kind yet found.

Prof. Gustav von Hayek, the author of the well-known "Atlas of Natural History" (published by Perles of Vienna), has received the gold medal for arts and sciences from the Emperor of Austria, in recognition of the excellence of the work referred to.

We learn from *Science* that Commander Bartlett's annual report on the operations of the U.S. Hydrographic Office makes a good showing for activity and enterprise. Lists of light-houses and "Notices to Mariners," in which bearings are given in degrees from true north, instead of magnetic bearings in points, as formerly, have been liberally published; the official correspondence with other hydrographic offices has been increased; and a complete set of the charts issued by all nations is kept on file, and is always at the service of the public for the determination of any questions relating to hydrography. The only vessel engaged in making surveys during the year was the *Ranger*, on the west coast of Mexico and Central America; but it is strongly recommended that new surveys be undertaken in several regions where they have long been wanted. The charts of the northern coast of South America are mostly based on old Spanish surveys dating back to 1794. "Watson's Rock," latitude 40° 17′ N., longitude 53° 22′ W., in the path of North Atlantic traders, has been reported so many times that its existence ought to be definitely settled or unsettled. The recommendation of previous hydrographers with regard to surveys of the Caroline and Marshall Islands, in the equatorial Pacific, should no longer be neglected; they lie in the belt of the trade-winds and westerly current, the natural highway of vessels crossing the ocean to Japan, China, and the East Indies, and require immediate examination. In the North Pacific alone there are over 3000 reported dangers that need decisive observation. In many cases the same island has half a dozen different positions, with as much as fifty miles between the extremes. It is urged that every naval vessel be provided with modern sounding-apparatus, by which even deep-sea measures can be quickly made, and required to sound wherever the charts show no depths reported within twenty miles on any side; and it is desired that a ship should be fitted out expressly to make investigations into ocean temperatures at all depths, and thus obtain data necessary to complete the determination of the actual oceanic circulation.

M. Guinet, a rich burgher of Lyons, having spent some years of his life and 200,000*l.* of his money in the erection and furnishing of a museum, recently opened in his native town, intended to illustrate the religions of the East, has further applied to have the establishment transferred to Paris, where it would be likely to interest and instruct a larger number of visitors. He has, in addition, offered to consign the whole into the hands of the Government under certain conditions, an offer which has been accepted. A number of priests belonging to the Buddhist and Brahmanic religions are to be brought to Paris, and at fixed salaries employed in translating historical and liturgical books connected with their respective faiths.

The French Government have bestowed fresh honours on the officers of the Meudon steering balloon, one of them having had his name put down on the list for the distinction of a "Chef de Bataillon," while another has been made a knight of the "Légion d'Honneur," and a third, who was wounded in preparing the hydrogen gas, has had the same distinction awarded him. At the same time that we observe the services of these gallant officers so well appreciated, we learn that the steering balloon has been dismantled without undergoing any new experiments, nor do we hear that the Commission appointed by the Academy of Sciences to report on the balloon has published any verdict respecting it.

The Municipal Council of Paris having been called on to vote on the question of a site for the Centennial Exhibition of 1889, have selected the Champ de Mars, the ground on which former exhibitions were held. This unexpected vote on a matter to which in the circumstances of the case great importance was attached has caused a considerable amount of sensation.

"Celsus and his Works" was the subject of the first of a course of lectures during the current session, delivered at the Faculty of Medicine in Paris, by M. Laboulbène. The course is to be devoted to a history of the principal discoveries in medicine and surgery, and the lectures are to appear in the *Revue Scientifique*.

A COMMISSION has been appointed by M. Cochery to determine the conditions of security requisite for laying electric cables to transmit currents of high tension. This step has been taken in connection with the experiments conducted at Creil and the Gare du Nord with the Marcel-Deprez system, as well as others which may be in preparation.

THE observer at the meteorological station on the summit of the Obir (Carinthia) reports that on October 11, at 8.15 p.m., he saw a beautiful display of St. Elmo's fire. The points of the vanes, the telephone wires, and the tops of the posts supporting this wire shone brilliantly in a whitish-blue light.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀), a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. John Roberts; a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. David McCance; a Montagu's Harrier (*Circus cineraceus*), European, presented by Lord Lilford, F.Z.S.; a Banded Gymnogene (*Polyboroides typicus*) from West Africa, a Gold Pheasant (*Thaumalea picta* ♂) from China, an Indian Python (*Python molurus*) from India, deposited; three Lions (*Felis leo*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE BINARY STAR α CENTAURI.—In the last number of the *Monthly Notices* of the Royal Astronomical Society, Mr. E. B. Powell, so favourably known for his excellent measures of double-stars, made during his residence in India, has a note in which he gives reasons for concluding that the period of revolution of this most interesting binary is longer than has been assigned by the later calculations of its orbit, and, instead of a period of 77½ years, which is about that found by Dr. Elkin, he considers that one of 86 or 87 years is better supported by the earlier observations, viz. those by Richaud at Pondicherry in December, 1689, and by Feuillée at Lima on July 4, 1709. The results of an investigation by Dr. Doberck, communicated to the writer early in 1879, rather tend to support Mr. Powell's conclusion. Dr. Doberck's elements, which are professedly only provisional ones, are as follow:—

Periastron passage	1875·12
	° ′
Node	25 32
Angle between the lines of nodes and apsides	45 58
Inclination	79 24
Excentricity	0·5332
Semi-axis major	18″·45
Period of revolution	88·536 years.

In this orbit the angle and distance at the epochs of the observations of Richaud and Feuillée would be:—

1689·95	Position, 14°·9	Distance, 9′·54
1709·51	,, 200·8	,, 14·74

ENCKE'S COMET.—The elements of this comet for the approaching perihelion passage are as follow, according to the calculations of Dr. O. Backlund of Pulkowa:—

Perihelion passage 1885, March 7·6523 G.M.T.

Longitude of perihelion	158° 32′ 45″·0	Mean Equinox 1885·0
,, ascending node	334 36 54·6	
Inclination	12 54 0·1	
Angle of excentricity	57 45 20·5	
Mean daily sidereal motion	1072″·97311	

The corresponding period of revolution is 1207·86 days. An ephemeris for January will appear next week.

BARNARD'S COMET.—Prof. Frisby of Washington has calculated elliptical elements of this comet from observations made at the Naval Observatory between August 12 and October 20, and therefore extending over sixty-nine days. The period of revolution in his orbit is 1878·65 days, or 5·143 years, but this element does not appear to be as yet very closely determined, much less so indeed than in the case of the second new comet of short period detected during the present year by Wolf. In Prof. Frisby's orbit the distance of the comet at aphelion from the orbit of Jupiter would be 0·705, the aphelion distance being 4·683, therefore considerably within the orbit of the planet; at the ascending node the comet's distance from the sun would be 1·552, and at the opposite node 3·942. Taking these conditions into account, it would appear probable that it has been long moving in its actual orbit. The comet, however, belongs most likely to the fainter class of those revolving in short periods, and in the present year has been observed under somewhat favourable circumstances: it approaches nearest to the earth when the perihelion passage takes place between a fortnight and three weeks earlier than in 1884. On November 20, M. Perrotin observing with the Gauthier-Eichens equatorial of the Observatory of Nice, aperture 0·38 m., found the comet near the limit of vision for that instrument; he remarks:—"Pour la rendre sensible à l'œil et bien saisir sa position exacte, on était obligé d'agiter legèrement la lunette en ascension droite, tantôt dans un sens, tantot dans l'autre." The position determined for that evening was as follows:—

Nov. 20 at 7h. 25m. 38s. Nice M.T. R.A. 22h. 38m. 21·85s., N.P.D. 97° 18′ 20″·4.

The Observatory of Nice (Mont-Gros), established through the munificence of M. Bischoffsheim of Paris, is in longitude 0h. 29m. 12·2s. east of Greenwich, and in latitude 43 43′ 16″·7.

GEOGRAPHICAL NOTES

THE correspondent of the *Times* with the Afghan Boundary Commission, writing from Khwaja Ali on October 16, describes the march of the expedition from Quetta to the Helmand. The geologist, Mr. Griesbach, describes the geological features of the country as much the same as those seen in the Pishin and Candahar country, viz. steep, deeply-eroded mountain ranges with a general strike of north, south to north-east, south-west, the intervening valleys being filled by Post-Tertiary deposits, which form extensive plains and glacis. The ranges of hills are more or less continuations of ranges, which are crossed by the Quetta-Candahar road. After leaving Kanak, one crosses the south-western end of the Ghaziaband range, which is composed of sandstone, shales, and grits of the "flysch" facies of the Eocene rocks. Beyond that range one enters the southern extension of the Lora plain of the Pishin. The white and coloured clays of the Siwaliks, seen from Dina Karez in the Pishin, are again seen (afar off) from Panjpai, and no doubt they underlie most of the Post-Tertiary deposits which form the surface of these wide valleys). The low ridges between Panjpai and Nushki are composed of sandstones, flaggy limestone beds, and friable shale, identical with the "Soliman" sandstone, and entirely belonging to the Lower Cretaceous series. The contact between the hippuritic limestone and the trap contains in the Candahar district gold (with traces of nickel) and galena ores. The water found below the surface is the natural drainage from the hills, contained in the gravels and sands of the Post-Tertiary fan deposits, inclosed between the clays of the Siwaliks below, and the recent conglomerate (a kind of kankar) above.

DR. CHAVANNE, who visited the Congo by order of the Brussels Geographical Society, has returned to Lisbon for a short period in order to recruit his health, which has suffered by the tropical climate.—Herr Flegel, who was preparing for a new expedition into the Benué districts, is also detained in Europe by ill health.—The Russian traveller, M. Piasecki, well known through his travels in China in 1874, is about to start on another exploring expedition to that country under the patronage of the Emperor of Russia and the Grand Duke Wladimir.

IN a recent number of the *Revue Scientifique* there is a long article by M. L. Simonin, on the geography of China. The area of the whole Empire of China is estimated at 11,574,356 square kilometres, *i.e.* the largest empire in the world next to that of Russia, which is 21,702, 230 square kilometres. China proper, however, is only 4,024, 690 square kilometres, *i.e.* two-fifths of Europe, seven times the size of France, and fifteen times that of Great Britain. With regard to the population of China it is not possible to give precise and absolutely trustworthy numbers, there being no proper official census in force in the Empire. The statistician of the Imperial Chinese Customs sets down the actual population of China at 250,000,000. A census drawn up in 1882 for fiscal purposes, and cited by the United States Minister in China, gives 255,000,000 as the number of the population. In the lower basin of the Yang-tse-Kiang as

many as 420 people are to be found crowded within the limits of one square kilometre. The total debt of the Government is reckoned at 266,000,000 francs, of which 214,000,000 francs have been contracted within the Empire itself, leaving only 52,000,000 francs of foreign debt. The army is composed of two large bodies: the Tartar army, including the Manchoos and the Mongols; and second, the Chinese army. The Tartar army, guarding Pekin, the frontiers, and the coast, comprises the army of Manchooria of 30,000 men, the Mongolian army of 20,000 men, the Turkestan army of 40,000, and lastly the army occupying the maritime provinces, numbering 100,000. The Chinese army proper is distributed throughout the eighteen provinces, and performs the functions of police in addition to its military duties. Its number ranges from 20,000 to 100,000 in each province, according to its population and its defensive requirements. The navy in 1879 was estimated to comprise fifty-six ships armed with 283 guns, and manned by 5860 marines. Since that date, however, the fleet has been largely developed.

L'Exploration states that the Geographical Society of Amsterdam is about to acquire the fac-simile of the most ancient map known, and which represents the Roman Empire as it was in the time of Augustus. It is formed of eleven folding maps, which make one large map 8½ metres in length. The original is in the Royal Library at Vienna, which purchased it in the sixteenth century from the estate of Conrad Peutinger of Augsburg, a circumstance which gave the map its name of *Tabula Peutingeriana*. Peutinger purchased it for 40 ducats. The original, which is dated 1265, was the work of a Dominican monk of Colmar.

THE deaths are announced of two Italian geographers and travellers, Eugenio Balbi and Carlo Guarmani. The former was the son of the celebrated Adrien Balbi, and was born at Florence in 1812. After several years' travel in Europe, he finally returned to Italy, where he devoted all his energy to the study of ethnography and geographical science. His principal works are: "Gea"; "I monumenti della geografia nell' evo medio e moderno"; "L'Italia nei suoi naturali confini." Guarmani had travelled widely, and in his last years was one of the correspondents of the geographical review of Milan, *L'Esploratore*.

THE Institute of Argentine Geography has decided to organise an expedition into the Andes of Patagonia. The explorers will leave Lake Nahuel-Huapi, and will then undertake a detailed investigation from a geographical point of view of the Argentine slope of the Andes, following it to the Straits of Magellan. The head of the expedition will be Capt. Moyano, who has been instructed to present a report to the Institute at the earliest possible date, indicating the plan of work, the instruments, and other objects necessary, as well as an approximate estimate of the expense. The Federal Government will be requested to grant the co operation of the troops stationed on the frontiers of Limay, as well as to send a sloop-of-war to act where possible in concert with the expedition.

A TEACHING UNIVERSITY FOR LONDON

IN connection with our leading article this week we append the following Plan for Promoting a Teaching University for London, which was discussed at the meeting:—

A sub-committee was appointed on Monday, November 10, to draw up a plan, in accordance with the objects of the Association for promoting a Teaching University which are as follows:—(1) The organisation of University Teaching in and for London, in the form of a Teaching University, with Faculties of Arts, Science, Medicine, and Laws. (2) The association of University Examination with University Teaching, and direction of both by the same authorities. (3) The conferring of a substantive voice in the government of the University upon those engaged in the work of University Teaching and Examination. (4) Existing Institutions in London, of University rank, not to be abolished or ignored, but to be taken as the bases or component parts of the University, and either partially or completely incorporated, with the minimum of internal change. (5) An alliance to be established between the University and the Professional Corporations, the Council of Legal Education as representing the Inns of Court, and the Royal Colleges of Physicians and of Surgeons of London.

The Sub-Committee, consisting of Lord Reay, Chairman, Prof. John Marshall, F.R.S., Ex-P.R.C.S., Dr. W. M. Ord, F.R.C.P., Mr. F. Pollock, Barrister-at-Law, Mr. R. S. Poole, British Museum. Dr. P. H. Pye Smith, F.R.C.P., Prof. G. C. W. Warr, King's College, Prof. A. W. Williamson, University College, and Sir George Young, met and considered the subject of reference, and submitted the following proposed plan of a Teaching University for London for the consideration of the Committee, on Monday, the 15th inst.:—

(*a*) THE CONSTITUTION OF THE TEACHING UNIVERSITY.—To be founded on (1) the *Faculties* or Constituent Bodies; (2) a *Board of Studies* for each Faculty; (3) a Governing Body or *Council*.

(1) *The Council.*—To consist of Members representative of—

(*a*) The several Faculties. The proportion of representatives of the Faculties to the whole number of the Council to be at least one-third.

(*b*) The Senate of the University of London.

(*c*) The Council of Legal Education.

(*d*) The Royal Colleges of Physicians and of Surgeons.

(*e*) It should be a point for future consideration whether other Public Bodies should be directly represented on the Council, *e.g.*, the Authorities of the British Museum, of the Royal Academy and Royal Society, of the Incorporated Law Society, and of the Institute of Civil Engineers.

(*f*) Colleges and other Educational Institutions associated with the University. The amount of representation and the qualification for direct representation on the Council to be determined, in each case, having regard both to the nature and the amount of the educational work performed by the Associated Institution.

(*g*) Endowing Bodies, *e.g.*, the Crown, if the Teaching University should receive State endowment; the Corporation and Companies of the City of London, if they contribute to endow the University.

Representatives of Associated Institutions and Endowing Bodies not to exceed one-third of the whole number of places on the Council.

(2) *The Boards of Studies.*—To be elected by each Faculty. Some additional Members might be appointed by the Council. The Board to advise in all matters relating to the Faculty, and to exercise authority in such matters as are delegated to it by the Council. Facilities to be provided for joint meetings and action of two or more Boards of Studies when necessary. The Board to appoint some or all of the representatives of the Faculty upon the Council. If any are appointed by the Faculty direct, they should also be *ex officio* Members of the Board.

(3) *The Faculties.*—To consist for electing purposes of—

(*a*) Teachers: being Professors, Lecturers, or persons of equivalent standing, in the Colleges or Educational Institutions associated with the University.

(*b*) Examiners for the time being in the Teaching University and in the existing University.

(*c*) Additional Members, to be appointed by the Council, on the recommendation of the Board of Studies.

There might also be Honorary Members of Faculties, including Graduates in that Faculty, of the Teaching University; Members of Convocation of the existing University according to their Degrees; recipients of degrees *honoris causâ*, and so forth; such Honorary Members having the right to attend and vote only at a General Meeting of the Faculty, to be summoned on requisition when necessary.

(*b*) RELATIONS OF THE TEACHING UNIVERSITY WITH OTHER BODIES.—(1) *The Existing University.*—There might be one Chancellor, with two Vice-Chancellors, the Teaching University and existing University constituting one University in two departments. The Degrees might, if necessary, be distinguished by their designation in some suitable manner. The Senate of the existing University would remain unaltered, would be appointed as at present, and would control the present Examinations and confer Degrees, without interference. Convocation might accept the Graduates of the Teaching University as full Members. The Teaching University might, so far as is practicable, find a place of meeting at Burlington House, together with the existing University.

(2) *The Professional Corporations.*—Degrees in Law, Medicine, and Surgery to be recognised as qualifying *pro tanto* for Call to the Bar or for Licence to practise, the power of Calling to the Bar or of conferring Licences to practise being reserved to the existing Authorities. The previous Examinations of the Teaching University to receive recognition by those Authorities, such as is now given to the Examinations of existing Universities.

(3) *Colleges, Educational Institutions, Special Schools, and Institutions for Purposes of Research.*—Each Associated Institution to remain unaffected in any way, save in so far as it might be willing to adopt the recommendations of the University Council.

The School of Law of the four Inns of Court to be an Associated Institution, and its Professors and Examiners to be Members of the Faculty of Law, but without further direct representation on the Council than that already given to the Council of Legal Education.

The recognised Hospital Schools of London to be Associated Institutions, and their Professors and Lecturers to be Members of the Faculty of Medicine.

The direct representation of the Hospital Schools on the Council being difficult, owing to their number, it might be provided that they should all have one representative, at least, on the Board of Studies of the Medical Faculty.

Schools of Fine Art and Technical Schools employing Teachers, some of whom are not engaged in what can be called, strictly speaking, University work, if composing part of an Associated Institution, to be admissible as Special Schools of the University, and their principal Teachers to be Members of the appropriate Faculties.

Junior Schools forming part of Associated Institutions to be admissible similarly as Special Normal Schools, for the purpose of training Teachers.

Institutions for purposes of Research to be admissible as Special Schools, and their Principals or principal Members to be eligible as additional Members of the appropriate Faculty.

Educational Institutions, of which the work is either in kind or quantity insufficient to entitle them to rank as Associated Institutions, while at the same time partaking of a University character, to be similarly admissible as Special Schools.

(*c*) Work of the Teaching University.—The Teaching University to obtain power to confer the usual Degrees, either by way of supplemental Charter to the University of London or otherwise, after such course of study and examination as may be determined on.

As means and opportunity will allow, the Teaching University to appoint Professors in the more advanced studies, and for purposes of original research.

The Council to negotiate with Associated Institutions for the increase of facilities for common attendance at lectures, laboratory work, and admission to Libraries and Museums, and for the concentration of teaching within one or more of such Institutions, or within the University itself, in such studies as may appear desirable.

The extent to which it may be found possible to blend the examinations of the Teaching University with those of the existing University, of the Professional Corporations, or of other Examining Bodies, to be determined hereafter, full liberty of action being reserved to the respective Authorities.

Professors, Lecturers, &c., who are Members of the Faculty, to have the title of "——— Professor, Lecturer, &c., of (or on) ———" in the proposed University; the first blank denoting the College or Institution with which they are connected, preceded by the title (if any) by which their Chair or other office is known.

Students in Associated Institutions and Special Schools to be at liberty to become Undergraduates in the Teaching University, or to obtain Degrees as at present from the existing University.

Signed on behalf of the Sub-Committee,

Reay, *Chairman*

NATURE-DRAWING [1]

Before explaining the objects aimed at in the new drawing classes proposed to be formed in University College School, to be called Nature-Drawing Classes, let us look back and note briefly what we have achieved up to the present time, and gather if we can from it what kind of foundation we have for the work we are about to do, and what our necessities are in order to secure success. Of the past I am able to speak with some authority, having been connected with the drawing classes in this school for nearly forty years. That we have achieved a very considerable success is proved by the high position these classes are known to hold as compared with similar classes in other public schools; also by the fact that every boy who has taken the "Trevelyan Goodall Art Scholarship" in the school and has competed for the Slade Scholarships in the Slade Schools of Fine Art in University College has, without an exception, succeeded in securing the object of his ambition, and in the case where two of our boys were competitors at the same time, they succeeded in carrying off both scholarships, and all in competition with students older than themselves.

Now it is evident that such remarkable success must rest on some very sound foundation. Though there is no doubt that our method of teaching may account in part for this, and in no small part, yet by far the larger part of the foundation of this success has been laid by the zeal, energy, and intelligence in teaching displayed by the assistant drawing-masters, and I desire frankly, and without any reservation whatever, not only to acknowledge their signal ability and their right to the merit due from the results, but also to acknowledge my own indebtedness to their loyalty in giving effect and unity to the method of teaching, without which our success could never have been secured. The teaching has hitherto ranged from the drawing of simple geometrical forms to the drawing of the figure from the antique, together with mechanical drawing, model drawing, and perspective. And now I have a word for the younger boys, who, sometimes, may find the repeated drawing of curved and other lines a little wearisome, but they may rest assured that they are doing valuable work, and acquiring an invaluable power, for it is mainly in the combination of these curved lines, in the perception of their grace, and the power to render them accurately and freely, that the expression of the most beautiful form, and even the recognition of it, at length becomes possible.

That curriculum in our public schools is best which has the greatest elasticity, and is not bound so closely within the four walls of precedent that it is deprived of the power to expand in any direction to meet the necessities of the times. That the teaching of drawing in our public schools has not advanced adequately to meet these necessities will be, in most cases, frankly recognised by the teachers themselves. But the fault does not lie at their door. It is the "governing bodies" of our public schools, and the outside public, who are to blame. The past low estimate of both alike as to the utility of drawing as a serious study has proved the detriment to its advance. Both have recognised in drawing little more than a sort of harmless amusement to keep children out of mischief when not otherwise employed. Both have been blind to the influence which the imitation of beautiful forms must needs have on the minds of the young, and, yet more, to the influence it must have in after life. A love for beautiful form goes far towards making a beautiful life. While due effect is given to the utilitarian side of education, the æsthetic side cannot be ignored, but through literature and art the æsthetic phase of the student's mind should be developed as widely as possible, and, as a help to this, Prof. Huxley has publicly stated his conviction that it should be made *absolutely necessary* for everybody for a longer or a shorter period to learn to draw, and that there is nobody who cannot be made to draw more or less well.

It is proposed to arrange the new nature-drawing classes under two broad divisions, namely, landscape-art and science-art. Let us deal first with the proposed study of landscape-art, and, in order to make the direction these studies are to take the more clear, it were as well to state the direction they are not to take. They are not to take their direction on the old lines of making, in a blind, ignorant way, copies from the flat to be "finished off" by the more or less facile pencil of the master, and sent home *as the work of the pupil* at the close of the term. The influence of such palpable dishonesty can only be bad, and the more bad because of the openness with which the fraud is committed. It may be asserted that no fraud is intended, but is not almost every child sensible that there is a very real fraud, to which he has been made a party without his consent, when he shows his drawings and is praised for work he is well aware is not his own? Moreover, do you think he does not recognise how frequently and *easily* the fraud succeeds? But enough; let us dismiss it—it is bad. In the "nature-drawing" classes in University College School, landscape-drawing from the flat will be used only to secure with the pencil and the brush that *technique* absolutely needful. Concurrently, lessons will be given in the shape of lectures on natural phenomena, towards inducing a close, intelligent observation of them, in the belief that a boy will not draw an object—a cloud or a tree from Nature—any the worse, or with any the less interest, because he knows something about it, some scientific facts concerning it. Drawing is a record

[1] An address by W. H. Fisk, in part delivered at University College School, Gower Street, London.

of thought as well as of observation, and the measure of thought, as applied to form, is in exact ratio to the knowledge of the causes of it, and the knowledge of them the measure of intelligent delight in observing and recording their results. Accept this as a fact—*art cannot be divorced from science*, for it is science which teaches us to see truly, and by art we render the truth we see. In representing the human figure, this has been a recognised fact for perhaps over two thousand years. They who have drawn the figure finely have been earnest students of anatomy. Yet the anatomy of landscape-forms has been persistently ignored by all but a very few. The recognition of the anatomy of landscape as an art-study is a very modern recognition indeed. Yet to see truly in order to render truly is of as paramount importance in the representation of landscape as in that of the figure. Individual form is a correlation of scientific facts, a knowledge of which enables us to understand its structure and to imitate its appearance with correctness. It is mainly with these that we have to do if we would represent a mountain, a tree, a cloud. It is true that all forms are modified by their environment—by a ceaseless struggle with the varying conditions by which they are surrounded—while the modifications are the result of scientific facts as the forms themselves are. So, if we would represent objects *truly*, science alone can be our guide; for it is science which teaches us to see truly, not through the medium of our fancy, but through the exercise of our intelligence. Thus, for example, in these nature-drawing classes, the structural forms of mountains of granite, downs of chalk, hills of limestone, will be presented and explained side by side with the forms as they at present exist, and which are the results of modifications produced by persistent disintegration and denudation owing to the action of rains, frosts, winds, glaciers, streams, &c., during vast lapses of time. So with the structural forms of trees and their environment—whether of Coniferæ on the limits of the snow line; or trees in a dense forest-growth or on the outskirts of a wood; within the Arctic Circle or in tropical regions; affected by climatic extremes, by drought or excessive moisture; the free access of light or through its deficiency; by the repeated action of winds mainly in one direction distorting the tree, or their influence in many giving a healthy stimulus to the circulation of the sap.[1] It is needless further to pursue the explanation of the plan it is proposed to carry out in landscape-art; enough has been explained to make clear the object in view and the method to be pursued. But the student must be prepared for many objections which will be raised: by painters careless of truth, and by some scientists who will insist on divorcing science from art because they feel their own minds chained by love of minute and beautiful detail, not thinking it possible for other minds to assert their freedom; by painters too lazy to enter the field of science, and who will assert that the mission of the artist is to represent what he sees, or rather what he fancies he sees, no matter whether he sees truly or falsely; or by people who, mistaking a certain deftness of handling for a true representation of natural phenomena, will exclaim, "Surely, if such landscape-art as we have has been sufficient in the past to secure public applause, will it not suffice to retain that applause for the art of the future? or are canvases to be crowded with illustrations of botany, geology, meteorology, bryology, and a host of other 'ologies,' and then to be called landscape-art?" Such talk as this is common enough, but it is sheer nonsense. To the true artist applause is a very small matter: he will not look to the market for the measure of his success, but he will gauge the quality of his own work, whether it be true or whether it be false. The one question with him is whether his picture is to be a painting of fancies which have no existence except in the idle mind of the ignorant painter, or is it to give us a representation of facts: in short, is it to be true or is it to be a sham? No true artist will ignore scientific truth, for he knows that it is next to impossible truly to generalise a multitude of like forms when he is ignorant of the special characteristics of any one individual form of the group. He will not ignore scientific truth, for that truth is the concrete foundation of all noble, all poetical art. There is one sovereign antidote to that poison so dreaded by some timid minds, viz. the chance that rigid illustration of scientific fact will dominate the work, and the antidote lies in the *individuality* of the artist. He will clothe all truth with the poetry of his own nature—with the force of his own character. He will be humbly and faithfully dependent on science for his *knowledge* of all form, but it will be on himself that he will depend for that *expression* of it through the medium of a psychical truth which is extra-scientific, and transcends in beauty the visible form of all natural truth, of which it is at once the sublimation and the epitome.

That division of the nature-drawing classes which I purpose to call science-art, presents in its plan a fourfold object. (1) To induce youths while yet at school to take up, seriously, some branch of natural science, with a view, eventually, to original investigation, and to afford them a power, both with pencil and brush, of accurately recording the results of their observation. (2) To supply that demand which Mr. Norman Lockyer informs us is now being made by scientific men, that students in science shall be able to draw. (3) To supply intelligent and artistic draftsmen for scientific purposes and for the illustrating of scientific works. (4) Mainly and especially to engender in young men, before they leave school to enter on the business of life, a love for the pursuit of scientific truth as being amongst the keenest amusements and the truest and most enduring pleasures of life.

In the ultimate purpose of any instruction lies the test of its future usefulness to the student and to society at large. The teaching of children has in it as much the making of the history of a nation as fighting battles and making laws, and earnest teaching is amongst the grandest employments of life, provided it be noble and useful and good. The teaching which is an inducement to a proper use of time goes far to create an environment which will be beneficial to maintenance and pleasure of life mentally and morally alike, and I know of no better use of time than that of scientific inquiry, which should be encouraged in all our public schools. So with drawing. By uniting it with the pursuit of science it will cease to be subject to that derogation it at present suffers through those who regulate, both within and without, the curriculum of our schools. But here in University College School the governing body is, as is well known, liberal to a fault, and the head master takes considerable interest in this new departure in the teaching of drawing.

Time will not permit me to dwell long on the plan to be adopted in the classes for science-art. At the commencement one or more scientific subjects will be selected. In connection with these the collecting of objects will be encouraged for purposes of investigation and illustration, but collecting for the mere sake of collecting will not be countenanced. Let us take entomology as an example. The student will capture the larvæ of a *few* moths or butterflies. Of each of these larvæ he will make careful coloured illustrations from time to time, according to the results of the changes they may undergo. Faithful drawings of the plants they are fed on will be required, also of any evidences of mimicry, defensive or otherwise. Further drawings will be required of the cocoons of such of the larvæ as form them, also of the chrysalis and of the fully developed insect (together with its eggs) and of whatever mimetic peculiarities it may present. From time to time original papers will be required stating minutely the observations made while the insect is being reared. After a time the more advanced pupils will be required to pursue their investigations into its anatomical structure and functions, with the use of the microscope.

A lucid mind will guide the hand to lucid drawing—the last is, as it were, a photograph of the first. The habit of clearly defining the object in the mind will lead to clear and definite work with the pencil. To students in science the securing of this power while at school will enable such to meet the requirements of science-teachers, and will be a source of economy of time and toil. This will form a branch of the teaching in the science-art classes. Moreover it will be the foundation for realising the third object in view, viz. to supply intelligent and artistic draftsmen for scientific purposes, and for illustrating scientific works. In this branch something more—much more—will be required of the pupil than faithful and intelligent exactness of outline of form. For instance, if the boy is drawing some vegetable form, he will be required to observe, closely, not only the peculiarities of the structure, but the *habit* which is the exemplar of the mind of the plant. Further he will be shown wherein the physical beauty of the plant resides, and wherein lies that beauty which is suggestive of some psychical power which, for a purpose beyond that of mere physical form, has tinted the butterfly's wing and the corolla of flowers fertilised by humming-birds. With such instruction there is no reason why the illustrations in works on natural history should not as far transcend most modern illustrations as these transcend those in a nurseryman's catalogue.

[1] Until the student can go direct to Nature he will draw and paint, in the higher classes, from water-colour studies which have been executed entirely out of doors, and of which a large number have been kindly lent by different artists.

But the chief aim of the science-art classes will be to encourage a pursuit of scientific truth for its own sake, not for the sake of displaying talent in making beautiful drawings to be praised for them, nor for the money to be got for them when drawn, but, *simply and only, for the sake of the* TRUTH, which will yield us pure and incessant pleasure all our lives, and engender a sincere reverence for the Creator who has clothed his truths in wrappages of beautiful blossoms, and pure crystals, and opalescent clouds; in wrappages, too, which appear mean and even ugly, but they are wrappages only; even sin—that, too, is a wrappage, and looks very ugly, and is very revolting, but it covers some good, some truth which lies hid in every human heart, if we will only seek to find it.

There is a vast amount of real art-power unutilised, and so wasted, in our public schools, through narrowness of purpose in the teaching. It has been so amongst ourselves, though what we have done we have done thoroughly. We have laid a sound foundation in close observation of beautiful form and acquisition of technical power in representing it. In adding to it these nature-drawing classes, we have nothing to unteach. The field of work is simply widened that the power may be the more effectually utilised with more pleasure and with greater profit to the student, not only while at school, but as a pursuit in after life, and possibly drawing many from pleasures which are ugly, coarse, bad, and fleeting. This is a view of nature-drawing which parents might think about not without profit to their children. The pursuit of scientific truth, whether in the shape of landscape-art or of science-art, is a very noble pursuit, a very lasting pleasure; besides which science and art cannot fail to be mutually benefited, mutually advanced, in the long run, by such a conjunction as this, for indeed art loses her right hand when divorced from science, and science loses her right hand when divorced from art.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following have been elected to the General Board of Studies:—Mr. H. M. Taylor, by the Special Board for Mathematics; Prof. Liveing, by the Special Board for Physics and Chemistry; Dr. Vines, by the Special Board for Biology and Geology.

The election to the Cavendish Professorship of Experimental Physics will take place on December 22. The endowment of the professorship is 850*l*. a year.

The provision of 100 additional microscopes for the Biology Schools has been sanctioned, and a small charge will be made to students for their use.

Mr. C. T. Heycock, of King's College, has been approved as a Teacher of Chemistry, under the regulations for medical study.

The Syndicate for obtaining plans for a Geological Museum and Chemical Laboratory has been re-appointed.

Clare College offers to give scholarships of from 40*l*. to 60*l*. for Natural Science by examination, beginning March 19 next. The subjects will be Chemistry and Chemical Physics, Botany and Geology. A fortnight's notice will be required. Candidates, who must be under nineteen on the day of examination, must also pass in Elementary Latin, Greek, and Mathematics.

It is announced that in the next Fellowship election at St. John's College (November 2, 1885) regard will be paid to candidates' original dissertations or other writings, the candidates to be prepared to be examined in the subject-matter of the same. Candidates may also be examined in special subjects chosen by themselves, provided they give full and precise information regarding such subjects not later than June 1. The performance of the candidates in the University and other examinations will be regarded.

SCIENTIFIC SERIALS

Journal de Physique, October 1884.—The constitution and origin of group B in the solar spectrum, by M. L. Thollon (one plate).—On the colour of water, by M. J. L. Soret.—The effect of the electrical state of the surface of a liquid on the maximum vapour-tension of the liquid in contact with the surface, by M. R. Blondlot (one figure).—On the measurement of the maxima and minima electromotive forces in cells with a single electrolyte, by M. Emile Reynier (two figures).—Standard cell for the measurement of electromotive forces, by M. Emile Reynier.—On the chemical theory of accumulators, by M. Emile Reynier.—On the electrolysis of solid glass, by E. Warburg.

Journal of the Russian Physico-Chemical Society (Physical Section), vol. xv., 1883.—On an air-calorimeter, by N. Hesehus.—On a differential air-calorimeter, by W. Preobragenski.—On the critical temperature of isomerides and bodies belonging to the same homologous series, by A. Nadejdine.—New application of Carnot's theorem, by B. Sresnewsky.—On an algebraic transformation and its applications to mathematical physics, by by N. Slouguinoff.—On the focal properties of diffracted rays, by M. Mertching.—On the peculiar properties of caoutchouc, by N. Hesehus.—Method of determining the mean tint of a multi-coloured surface, by Th. Petronchewsky.—On the cause and the law of the change of electrical resistance of selenium by the action of light, by N. Hesehus.—On the relation between the magnetic moment of a bundle of iron wire, its mass, and the diameter of the constituent wires, by P. Bakmetieff.—Note on organ-pipes, by P. Bakmetieff.—On some phenomena of permanent magnetism, by P. Bakmetieff.—On the luminous phenomena accompanying electrolysis, by N. Slouguinoff.—On the theory of gratings traced on curved surfaces.

Royal Academy of Belgium, Nos. 9 and 10, 1884.—Among other communications is a paper by Dr. J. MacLeod describing some interesting particulars respecting the structure and homologies of the anterior intestine of the *Arachnides*. In the *Phalangides* he has found a gland of the same nature and function as the coxal glands recently described by Prof. E. Ray Lankester as belonging to the *Limules*, the *Scorpionides*, and the *Araneides tetrapneumones*. In the *culs-de-sac*, moreover, of the male gland of the *Trombidium holosericeum*, he has found, in all the individuals examined by him, ovules situated between the mother-cellules of the spermatozoides, though there was no question there of a functional hermaphroditism.—A paper by Emile de Borchgrave gives a graphic sketch of the history of Etienne Douchan, Emperor of Servia, and the Balkan Peninsula in the fourteenth century, and of the events which led up to the battle of Kossovo, the grave of the liberty and greatness of Servia.

Cincinnati Society of Natural History.—In the October *Journal* are two papers by U. P. James: one describing four new species of fossils from the Cincinnati group, the other treating of Conodonts and fossil annelid jaws.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, December 11.—J. W. L. Glaisher, F.R.S., President, in the chair.—The Rev. T. C. Simmons, Christ's College, Brecon, and Mr. W. J. Ibbetson, Clare College, were elected members.—Mr. Tucker read a paper on a group of circles connected with the nine-point circle considered as the locus of the intersections of orthogonal Simson lines. If PL, PM, PN are the perpendiculars from any point of the circum-circle on the sides BC, CA, AB of ABC, then LMN is a Simson line: if POP' be a diameter, then the Simson line $L'M'N'$, corresponding to P', intersects LMN at right angles in a point Q, on the nine-point circle, which is also the inscribed circle of the tricusp, enveloped by the Simson lines. These properties were stated in a paper by Steiner ("Crelle," Band liii.). In the present paper points l, m, n are taken on PL, PM, PN, such that $Ll = K.PL$, $Mm = K.PM$, $Nn = K.PN$. It was shown that the lines $l\,m\,n$, $l'\,m'\,n'$ intersect at right angles on a system of circles whose centres lie on the line connecting the circum-centre and ortho-centre (H) of ABC, that the sets of Q points (as above) lie on another straight line through H: that the circles are inscribed in tricusps, the points of contact lying on three straight lines symmetrically situated and passing through H. In the special case of nul-radius, *i.e.* when the (K) circle becomes the ortho-centre, it was seen that the images of any point on the circum-circle with regard to the three sides lie on a straight line through H.—Mr. Tucker then read parts of a paper by Mr. R. A. Roberts, entitled "Notes on the Plane Unicursal Quartic."—Two posthumous notes by the late Dr. Spottiswoode, P.R.S., were communicated, viz. on quadratic transformations, and to find whether a (certain) quadratic transformation be possible.—The Treasurer (A. B

Kempe, F.R.S.) made a short communication as to the mode of proof of the well-known theorem that, if $A\,D\,B\,E\,C\,F\,A$ be a hexagon in a plane, and if $A\,B\,C$ be collinear and $D\,E\,F$ be also collinear, then the intersections of the opposite sides of the hexagon are also collinear.—Mr. G. Heppel stated the following property of the equation to a central conic, $ax^2 + 2hxy + by^2 + c = 0$, which he had not met with in the ordinary text-books. The co-ordinates being rectangular, then, in the case of the ellipse, if $\frac{h}{c}$ be $+$ ve, the major axis passes through the first quadrant; in the case of the hyperbola, if $\frac{h}{c}$ be $-$ ve, the transverse axis passes through that quadrant. This property is proved by supposing the equation transformed to $\frac{x^2}{p^2} \pm \frac{y^2}{q^2} = 1$, and then transforming back again, so as to make the equation identical with the original equation. The comparison of coefficients gives the above law.—The President communicated a result he has obtained in elliptic functions, which will appear in a forthcoming paper.

Zoological Society, December 2.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—Col. Biddulph exhibited a stuffed specimen of the Wild Sheep of Cyprus (*Ovis ophion*), sent for presentation to the British Museum by Sir Robert Biddulph, the High Commissioner of Cyprus.—Col. Biddulph also exhibited three heads of the Wild Sheep of Beluchistan, named *Ovis blanfordi* by Mr. Hume, and drew attention to their similarity to *Ovis cycloceros* from the Salt Range, which led him to express doubts as to the distinctness of *Ovis blanfordi* as a species.—The Secretary called the attention of the meeting to the death, on July 5 last, of the Greater Vasa Parrot (*Coracopsis vasa*), presented to the Society by the late C. Telfair, Esq., in July 1830, which had thus passed fifty-four years in the Society's Gardens, and made some observations on a peculiar habit of this species.—A communication was read from the Rev. A. M. Norman and the Rev. T. R. R. Stebbing, containing an account of the first portion of the Crustacea Isopoda dredged during the expeditions of the *Porcupine*, *Lightning*, and *Valorous*. The memoir contained descriptions of the representatives of the three families Tanaidæ, Apseudidæ, and Anthuridæ obtained during the several expeditions. A great number of new forms, chiefly from deep water, including several genera (*Sphyraphus*, *Alsotanais*, and *Tanaella* among the Tanaidæ, and *Anthelura*, *Hyssura*, *Cyathura*, and *Calathura* among the Anthuridæ), were described.—Mr. G. E. Dobson, F.R.S., exhibited a diagram designed to illustrate the evolution of the Mammalia, after Huxley.—Prof. F. Jeffrey Bell read the fifth of his series of studies in Holothuroidea. The present paper gave some further information on the characters of the Cotton-Spinner (*Holothuria nigra*).—Mr. J. Bland Sutton read a paper on the parasphenoid, the vomer, and the palato-pterygoid arcade of the vertebrated skeleton. Mr. Sutton came to the conclusion that the parasphenoid of fishes was the homologue of the vomer of mammals.—Mr. G. A. Boulenger, F.Z.S., read some notes on the edible frogs introduced into England, which he referred to two forms—*Rana esculenta typica* of France and Belgium, and *Rana esculenta lessonæ* of Italy.—A communication was read from the Count T. Salvadori containing remarks on certain species of birds from Timor Laut.—A communication was read from Mr. E. P. Ramsay, C.M.Z.S., containing the description of a supposed new species of Flycatcher from New Guinea, proposed to be called *Rhipidura fallax*.—Mr. F. Day read the third of his papers on races and hybrids among the Salmonidæ. The author gave an account of how the salmon, which had been raised in fresh water at Howietown, had been artificially spawned; and pointed out that all the hybrids between the salmon and the trouts had proved sterile, while the hybrids between the trouts and the chars had proved fertile.

Geological Society, November 19.—Prof. T. G. Bonney, F.R.S., President, in the chair.—Nicol Brown, James Charles Chaplin, Herbert W. Hughes, and Rev. Samuel Pilling were elected Fellows; Prof. A. L. O. Descloizeaux, of Paris, a Foreign Member, and Prof. Hermann Credner, of Leipzig, a Foreign Correspondent of the Society.—The following communications were read:—Note on the resemblance of the upper molar teeth of an Eocene mammal (*Neoplagiaulax*, Lemoine) to those of *Tritylodon*, by Sir Richard Owen, K.C.B., F.R.S. In this paper the author referred to the genus *Neoplagiaulax*, described by M. Lemoine from the Eocene of Rheims, as presenting premolars so like those of the Mesozoic genus *Plagiaulax* as to have suggested the above name, while the true molars in the upper jaw resembled those of South African genus *Tritylodon* even more nearly than those of *Microlestes* and *Stereognathus*, with which the latter were compared. The lower molars of *Neoplagiaulax* have only two, instead of three, longitudinal series of tubercles; and the author suggested that this may have been the case also in *Tritylodon*; and that the detached molars, on which the genus *Microlestes* is founded, may also belong to the lower jaw.—On the discovery in one of the bone-caves of Creswell Crags of a portion of the upper jaw of *Elephas primigenius*, containing, *in situ*, the first and second milk-molars (right side), by A. T. Metcalfe, F.G.S. The specimen exhibited to the Society and now described was obtained from one of the Creswell bone-caves, before the commencement of their systematic exploration by a Committee of the British Association. The bone-caves are in the Lower Magnesian Limestone of the Permian, not far from the southern limit of that deposit near Nottingham. The locality was described, and it was shown that the ravine in which the caves occur has been cut in the limestone by the little river Wollen, which probably began by excavating a cavern the whole length of the ravine. The roof of this cavern must have fallen in, and the minor lateral caverns, in which bone-deposits are found, are now similarly being converted into side ravines. The fossil was found in "Pin-Hole Cave," the most westerly on the north or Derbyshire side of the ravine, about six inches below the base of the surface-soil, here four inches deep. The cave has been described in the Society's *Journal* (vol. xxxi. p. 679), by Rev. J. M. Mello, who in 1875 obtained from this spot bones of the Arctic fox (*Canis lagopus*). As the particular mammoth teeth (first and second milk-molars of the upper jaw) occurring in the fossil were wanting in the National Collection, the author has undertaken to present the specimen to the British (Natural History) Museum.—Notes on the remains of *Elephas primigenius*, from the Creswell bone-cave, by Sir R. Owen, K.C.B., F.R.S. The author noticed the various descriptions by Cuvier and himself of milk-molars of *Elephas primigenius*, and pointed out that all hitherto known were found detached. The present is the first known occurrence of the two earliest milk-molars *in situ*. The specimen discovered by Mr. Metcalfe is a portion of the fore part of the maxilla of a very young elephant with the teeth of the right side preserved, the corresponding teeth of the left side and their sockets having been broken away. Of the two teeth thus obtained descriptions and measurements were given. The first tooth is much worn, but only the anterior portion of the second has undergone wear, the two hindmost divisions of this tooth not having risen into use. It is shown that these first teeth of *E. primigenius* differ much less from the corresponding milk-molars of the Indian elephant than the later teeth do, the thickness of the constituent enamel-plates being but little less in proportion, and the principal distinction being the greater relative breadth of the second molar, especially towards the base of the crown.—On the stratigraphical position of the Lower and Middle Jurassic *Trigoniæ* of North Oxfordshire and adjacent districts, by Edwin A. Walford, F.G.S. The author spoke of the value of the *Trigoniæ* as stratigraphical guides, and of the wealth of the Oolitic deposits of North Oxfordshire in number of species as well as of individual forms. He alluded to the recent discovery by Northampton geologists of *Trigonia literata* and *T. pulchella* in the centre of their county. By the presence of certain *Trigoniæ* as well as of corals and bored stones he endeavoured to prove the extension of a stratum at the base of the *Clypeus*-grit at Fawler, as far as Hook Norton, also in North Oxfordshire, where the bulk of the Inferior Oolite was of an altogether different type. In Mr. Walford's list were nearly thirty species and varieties from the Bajocian beds. To the lower horizons there belonged but one local form, and no species of special stratigraphical value. The presence of a few other fossils supposed to be characteristic was the only evidence of beds below the zone of *Ammonites murchisoniæ*. Series C, which appeared to be of the age of the lower *Trigonia*-grit, had yielded the greater part of the *Trigoniæ* mentioned, several of them being peculiar to the horizon, whilst others were local species. The higher beds had yielded some apparently undescribed forms, whilst hitherto unrecorded species were quoted from the Great Oolite and Forest Marble. One species (*T. lycettii*) was described as new.

Chemical Society, December 4.—Dr. Perkin, F.R.S., President, in the chair.—The following papers were read:—

On calorimetric determinations of magnesium sulphate, by S. U. Pickering. The author finds that, when the ordinary hepta-hydrated salt is heated to 100°-130°, it retains about $1\frac{1}{9}$ molecule of water. This excess of one-ninth may be expelled by heating to 150°-160°, but, if this temperature be exceeded, some anhydrous salt is formed. The numbers obtained with the monohydrated salt were 12,131 cal.; with the anhydrous salt, 20,765 cal.—On condensation compounds of benzil with ethyl alcohol, by Miss M. E. Owens and Dr. F. R. Japp. By the protracted action of very dilute alcoholic potash upon benzil in the cold, the authors have prepared in large quantity a body, $C_{30}H_{24}O_4$, fusing at 200°-201°, and crystallising from alcohol with a molecule of alcohol of crystallisation. No acetyl derivative could be prepared. A second condensation-product, $C_{46}H_{34}O_4$, fusing at 232°, was also obtained.—Note on the solubility of certain salts in fused nitrate of soda, by F. B. Guthrie. The author has experimented with the sulphates, chromates, and carbonates of barium, strontium, calcium, and lead.—On certain derivatives of isodinaphthyl, by A. Staub and Watson Smith. The authors have endeavoured, by gentle oxidation of this body, to form the corresponding naphthoic acid. Cold strong nitric acid, however, produces a tetranitro body; dilute nitric acid in sealed tubes formed phthalic acid, and permanganate gave a similar result. Chromic acid in glacial acetic acid produced isodinaphthylquinone, a yellow amorphous powder melting at 250°-260°.

EDINBURGH

Mathematical Society, December 12.—Mr. A. J. G. Barclay, President, in the chair.—Mr. P. Alexander, Lady Margaret's College, Glasgow, contributed a paper on failing cases of Fourier's theorem, remarks on which were made both by Dr. Muir, who read the paper, and by Prof. Chrystal.—Dr. Muir gave a note on a function of two integral arguments; and Mr. A. Y. Fraser discussed the number of conditions determining geometrical figures.

DUBLIN

Experimental Science Association, November 19.—On Boakes's siphons of sulphur dioxide, by Prof. E. Reynolds, F.R.S.—Photometric measurement of lighthouse illumination, by T. Syle, University student.—On photometers made of paraffin, by J. Joly, B.E. This was an arrangement based on the remarkable difference of appearance presented by a piece of cracked paraffin about the plane of the crack, if placed in an unequally illuminated field. Two similar slabs of paraffin laid together on smooth faces show this effect very well. If the illumination about the plane of contact be brought to equality, the appearance of discontinuity vanishes. The close proximity of the fields to be compared confers great sensibility on the arrangement. The effect is due to the complete dispersion of the light in the translucent paraffin, thereby causing a large amount of it to be totally reflected at the plane of contact, across which, therefore, but little of the light received on either side passes.

PARIS

Academy of Sciences, December 8.—M. Rolland, President, in the chair.—Note on the photograph of a tornado taken by J. N. Robinson Howard last August in Dakota, United States, by M. Faye.—Final researches on antiseptic intravascular coagulation, by M. L. Gosselin.—Observations of Wolf's Comet made with the 8-inch equatorial at the Observatory of Bordeaux, by M. G. Rayet.—Observations of the same comet made with the meridian circle at the same observatory, by M. G. Rayet.—On the inversion of the abelian integrals, by M. Appell.—On a trigonometric formula of interpolation deduced from two formulas already established applicable to even and odd functions respectively, by M. G. Fouret.—On a generalisation of continuous fractions, by M. H. Poincaré.—On the integrals of certain functional equations, by M. G. Kœnigs.—Note on the numerical results required for the calculations of compressed gas manometers, by M. E. H. Amagat.—On the application of Ingenhouz and de Senarmont's processes to the measurement of the relative thermic conductibilities of different substances considered as isotropic, by M. Ed. Jannettaz.—On some practical processes for examining the luminous spectra of bodies to which the method of Lecoq de Boisbaudran is inapplicable, by M. Eug. Demarçay.—On ferrocyanhydric acid and the nitroprussiates, by MM. A. Étard and G. Bémont.—On the optic inactivity of the cellulose of cotton, and on the rotatory power of the gun-cotton of photography, by M. A. Béchamp.—Chemical analysis of the so-called "*porte-graine*" beetroot in the second year of its growth, by M. H. Leplay.—On the inertia of the retinal apparatus and its variations according to the exciting colours, by M. Aug. Charpentier. From experiments made during the last few years, the author concludes that the inertia increases with the refrangibility of the stimulating rays. Hence more light is absorbed or used up in producing the luminous sensation for the blue than for the green rays, for the green than for the yellow, and so on to the red. He further shows that any increase of intensity for any given colour requires all the more light in proportion to its greater refrangibility.—On the disease of the vine known by the name of *pourridié*, by MM. G. Foex and P. Viala. This disease, which is common in the South of France, and especially in Provence and Roussillon, is attributed to a species of fungus first observed by R. Hartig, and by him named *Dematophora necatrix*.—On the presence of the middle carboniferous measures in Anjou, by M. Ed. Bureau.—The results are given of a geological survey of this district undertaken during the present year by the author and his brother, the Director of the Natural History Museum of Nantes.—Tables of atmospheric movements between the parallels of latitude 30° S. and 80° N. for November 20, 1879, and January 1, 1880, based on the barometric charts prepared by M. Léon Tisserenc de Bort, by M. Poincaré.

VIENNA

Imperial Academy of Sciences, November 13.—Researches into the intimate structure of striated muscle-fibre, by A. Rollett.—Determination of the orbit of the planet *Adria*, by E. von Hœrdtl.—Remarks on the physical constitution of the atmosphere, by N. Herz.—The botanical results of Polack's expeditions to Persia in the year 1882, by O. Stapf.—Report on the plants collected by F. Luschan in Lycia and on the Nimroud Dagh, by the same.

THURSDAY, DECEMBER 25, 1884

THE "CHALLENGER" REPORTS

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873-76 *under the Command of Capt. George S. Nares, R.N., F.R.S., and Capt. F. T. Thomson, R.N.* Zoology—Vol. X. (Published by Order of Her Majesty's Government, 1884.)

VOLUME X. of the "*Challenger* Reports" consists of over 630 pages of text, and is illustrated by 80 plates; it contains Parts xxvi. to xxx. of the Zoological Reports, all of which have been brought out under the able management of Mr. John Murray. It speaks a great deal for the energy and speed with which the publication of these Reports is conducted, when one notes that the whole of the manuscript of this large volume was only handed in between July 1883 and July 1884, and that a portion of Dr. R. Bergh's memoir had to be translated.

The Report on the Nudibranchs is by Dr. R. Bergh. Judging from the number and variety of species of this group already described from tropical seas, it is probable that it is to the tropics we should look for the head-quarters of the group, and no doubt many and interesting species are yet to be discovered there. As few shallow-water dredgings were made during the cruise of the *Challenger*, it is not to be wondered at that the number of Nudibranchs collected was but twenty-five, including only one deep-sea form. The majority of the forms belonging to the Phylliroidæ and Æolidiadæ collected during the cruise are pelagic, and are represented by the genera Phylliroë, Glaucus, Fiona, &c.; some are littoral, such as *Janolus australis*, a single specimen of which was taken in the Arafura Sea, and one like the last referred to a new genus and species, *Cuthonella abyssicola*, was taken with the trawl in the Faroe Channel from a depth of 608 fathoms. Several new species belonging to the Tritoniadæ are described. Of the Dorididæ, two new genera and several new species are diagnosed. Of these the most interesting is *Bathydoris abyssorum*. This differs from all others of the family in the semi-globular form of the body, which is somewhat like that belonging to the genus Kalinga of Alder and Hancock, and which it also resembles in the characters of its branchia, these being composed of several separate branchial tufts, also in the development of soft conical papillæ upon the back. It has no frontal appendage, and the dorsal margin is very slightly pronounced. This new genus would appear to form a remarkable connecting link between the Tritoniadæ and the Dorididæ. The only specimen found was taken from a depth of 2425 fathoms, at Station 271, in the middle of the Pacific. Mr. Murray tells us that the body of the living animal was gelatinous and transparent, the foot was of a dark purple colour, the tentacles brown, and the gills and other external organs orange.

In an appendix, Dr. Bergh describes the only Onchidium in the *Challenger* collection as *O. melanopneumon*. Only one specimen was taken in shallow water, at Kandara, Fiji. Although some would regard the Onchidia as allied to the Nudibranchs, Dr. Bergh considers this view entirely erroneous. With regard to their phylogeny they have really nothing to do with Nudibranchs, and in a quite recent article in Gegenbaur's *Morphologisches Jahrbuch* (Band x. Heft 1, p. 172), he refutes the recent views of J. Brock. For comparison with the new species details of the anatomy of *O. tonganum* and *O. verruculatum* are given. This Report is illustrated by fourteen plates, for the most part devoted to anatomical details.

Dr. L. von Graff's Report on the Myzostomida collected during the voyage may be regarded as in some sense a continuation of his monograph on this interesting and little-known group. Of the 68 species enumerated in this Report, 52 appear as new. These Myzostomes are small disk-shaped animals, living attached to Crinoids, about whose affinities there has been up to the present a good deal of doubt, some placing them among the Worms near Tomopteris, others, as Dr. von Graff, among the Arachnids near the Tardigrades; and the discovery of a new form among the *Challenger* collection seems to confirm the correctness of this latter view. The author's class of Stelechopoda embraces the Tardigrades, Linguatulids, and Myzostomes, thus constituting a group of very lowly organised Arthropods. This Report shows that the Myzostomida do not form so uniform a group, either as to their habits or structure, as was formerly thought. It is prefaced by a very neat though brief account of the general structure of Myzostoma as far as it is known, with a graphic coloured diagrammatic representation and most minute details as to the general morphology, from which we condense the following important statements. While all the hitherto known forms were characterised by the peculiar radial arrangement of the organs of the body, several species are here described in which this arrangement is entirely lost; in some (*M. folium*) the body is greatly lengthened and the parapodia and suckers are found arranged in two parallel lines, while in a new genus (Stelechopus) not only has the external radial symmetry disappeared, but not even are the muscular septa and parapodial muscles convergent; hence, if, as the author believed long ago, the radial arrangement was an adaptation to the mechanism of fixation, or of the peculiar type of fixation, the want of it as in Stelechopus, which doubtless is a freely moving form, must be regarded as the primitive arrangement, and thus intensifies the affinity to the Tardigrades. It is interesting to find several forms entirely unprovided with suckers, though in some they may exist as mere rudimentary bodies; in one species (*M. calycotyle*) the suckers are stalked. The suggestion so aptly made by von Willemoës-Suhm that some of the Myzostomida were in all probability diœcious, has been amply verified by Dr. von Graff's researches. The two sexes when inhabiting the same cyst are at times unlike in appearance, the female being usually fifty to a hundred times as large as the male. The cyst-producing Myzostomes are of importance alike to the zoologist and the palæontologist, for these cysts have been found on the stalks of fossil Pentacrini, and as Dr. von Graff is continuing his investigations into the fossil form, he will be most grateful to any palæontologists who, having collections of fossil Crinoidea under their care, would examine the specimens and if they should notice the appearance of little pustules at the base of the pinnules, would communicate the facts to him. Of the sixty-seven species of Myzostomes

described, it must suffice to mention that elaborate illustrations are to be found of all the new ones, while Plate XVI. is altogether devoted to the illustrations of *Stelechopus hyocrini*. The body in this new type has a general similarity to a Tardigrade. Unfortunately the few specimens found being mounted in Canada balsam were somewhat altered in contour, but enough remained to surely indicate that the lateral margins of the body are nearly parallel in the middle, and become somewhat narrowed at either end. There is a conical caudal appendage. The largest specimen measured 3·5 mm. long, with a greatest diameter of ·9 mm.; the cuticle was chitinous; the parapodia, five on each side, were independent in action one of the other. The specimens were taken from species of Hyocrinus and Bathycrinus, off the Crozets, at depths of 1600 and 1375 fathoms. All the beautiful plates (sixteen in number) are from drawings by the author.

Dr. P. P. C. Hoek concludes his Report on the Cirripedia by the present series of chapters on the anatomy of the group. Unfortunately, the new forms of the deep-sea material being often represented by single specimens, it was impossible to work out their anatomy in any detail; but some excellent work has been done on forms formerly known. Thus the subject of the "complemental" males of Scalpellum is treated of, and every justice is done to the investigations of Darwin, who in 1851 first called attention to the strange phenomenon. "When we consider how much the methods of microscopical research have been improved in the thirty years which have elapsed, and that the male of *Scalpellum vulgare* which Darwin investigated is only 0·7 mm. in size, we can only wonder at the thoroughness of the information which he has given, and at the soundness of the conclusions at which he arrived." Dr. Hoek observed the complemental male in nineteen out of the forty-one new species described in the first part of the Report, but the unique specimens were not, and could not without spoiling them, be thoroughly examined. The structure of these males varies: some do not show a division of the body into a capitulum and a peduncle; a second group, while not showing either, are furnished with rudimentary valves; and a third not only have these latter but also show a distinct capitulum and peduncle. Another chapter treats of the anatomy of the complemental male in *Scalpellum ornatum*, one of the largest known. The subject of the Cypris-larvæ, of the segmental organs in the Cirripedia, of the cement apparatus, of Darwin's "true ovaria" (believed to be a pancreatic gland), the eye in Lepas, and the gynœcial organs, are also treated of and illustrated in six very beautifully executed plates from drawings by the author.

During the *Challenger* voyage human crania and skeletons were collected at several of the ports at which the ship called. These were intrusted to Prof. W. Turner for examination, and his first Report on the Human Crania forms part of the present volume. The crania were from the Admiralty Islands, the Sandwich Islands, the Chatham Islands, New Zealand, Australia, Terra del Fuego, Patagonia, and the Bush Race from South Africa. In another Report the other bones brought to England will be described. In the present Report, Prof. Turner has not restricted himself to the examination and mensuration of the skulls collected during the *Challenger's* voyage, but has, whenever possible, studied along with them skulls from the same localities, so that his Report may be looked on as an essay on the craniology of certain races of man. In all, there are described and tabulated one hundred and forty-three crania from aboriginal people who had lived in a state of uncivilisation. Not one of the skulls examined was metopic, though in a young male Australian, a Loyalty Islander, and in two New Guinea skulls traces of the frontal suture were seen in the glabella. In no skull was the malar bone either wholly or partially divided into two by a suture. In the skull of one Chatham Islander a wormian bone attained the magnitude of an intraparietal bone In a good many of the crania epipteric bones were found in the pterion on one or both sides, but Prof. Turner points out that the squamoso-frontal articulation in the region of the pterion is to be regarded as an individual peculiarity, and is not a racial character. In each group of skulls, except the Fuegian, specimens with an infra-orbital suture were met with, a suture which, though of by no means rare occurrence in the human skull, has had very little attention paid to it by anatomists. A mesial third occipital condyle was present in an Admiralty, a Sandwich, a Chatham Islander, and in a New Zealander. As several of the peculiarities noted are normal conditions in other mammals, they must be regarded when occurring in man as reversions to a lower type. It becomes of interest, therefore, to inquire if such reversions occur more frequently in savage than in civilised races. To such an inquiry Prof. Turner answers, that, while the number of skulls he reports on is certainly too limited to base any broad generalisations on as to the relative frequency of occurrence of particular variations in the different races, yet there is obviously a larger proportion of important variations to be met with among them than would occur in a corresponding number of skulls of the white race. As results of the study of the races of men described in this Report, Prof. Turner points out that in South Africa, in the southern part of South America, and in Australia, races of men exist distinguished by the small capacity of their crania, by their low intellectual development, and in the case of the Bushmen and Fuegians, by their small stature and generally feeble physical configuration. The Australians and the now extinct Tasmanians were under the average size of Europeans. In the islands to the south and east of the great Asiatic continent, the Andamanese and other Negrito tribes are distinguished by their small stature, microcephalic crania, and low state of intelligence. "It is not unlikely that these people may in the early unwritten periods of human history have had in their respective continents a much wider range of distribution than at present, and have been gradually pushed southwards into their present restricted areas by the advance of the races, more powerful in both intellectual and physical development, which we see around them. If on their displacement they failed to mix with their invaders, their physical characters would remain pure. For isolation and interbreeding carried on through many centuries would necessarily preserve and even intensify the characteristic peculiarities of each race." This Report is accompanied by an atlas of seven plates.

The concluding Report in this volume is on the Cheilostomatous Polyzoa, by George Busk, F.R.S., with thirty-six plates, of which a detailed notice, by Dr. George J. Allman, appeared in our last week's number.

GEODESY AND MEASURES OF PRECISION

A Treatise on the Adjustment of Observations, with Applications to Geodetic Work and other Measures of Precision. By T. W. Wright, B.A., C.E., late Assistant Engineer United States Lake Survey. (New York: D. Van Nostrand, 1884.)

THIS treatise will be found a valuable addition to the literature of geodetic operations; the title is, however, misleading,—it implies a discussion of the various corrections required to allow for the effects of temperature, refraction, &c.; such corrections, however, are either omitted or only superficially dealt with, and the principal subject-matter is the adjustment of unavoidable errors by the method of least squares.

The work commences by a discussion of the various causes of error, and several practical hints are given as to how to diminish them. A remark in connection with personal error is worth quoting:—"A good observer, having taken all possible precautions with the adjustments of his instruments and knowing no reason for not doing good work, will feel a certain amount of indifference towards the results obtained. The man with a theory to substantiate is rarely a good observer, unless, indeed, he regards his theory as an enemy and not as a thing to be fondled and petted."

In the second chapter the usual law of error is stated, and the method of least squares is deduced therefrom, together with formulæ for calculating the mean square error, the probable error, and the average error. The author points out that the name "probable error" is unfortunate, and so we think; he is also of opinion that the average error might with advantage be more used than it is at present as a measure of the precision of a set of observations. This chapter is concluded by a most instructive discussion on the laws of error, based on various assumptions as regards the number of sources of unavoidable error. It is first supposed that there is only one source of error, and that all errors between certain limits are equally probable; the curve of error then becomes a finite straight line. The next case considers two independent sources of error, the curve then becomes two straight lines intersecting on the axis of y at an angle of 45°. In the third case three sources of error are assumed, and the curve of error is shown to consist of three parts, which together form a close approximation to the usual curve of error. The method of least squares is further developed in the succeeding three chapters, and applied to the adjustment of the direct observations of one unknown, to indirect and to condition observations. Various methods of solving the numerous resulting equations are given, both rigorous and approximate; amongst the latter the method of solution by successive approximations as used in reducing the primary triangulation of the Ordnance Survey of Great Britain is strongly recommended. The author also recommends the use of a calculating machine, or of Crelle's Tables, in order to diminish the arithmetical labour.

The remainder of the work is devoted to applying the foregoing to triangulation, to base-line measurements, to spirit levelling, to trigonometrical levelling, to the graduation of line measures, to the calibration of thermometers, and to the discovery of empirical formulæ. The application to triangulation is treated very fully, and several methods of solving the necessary equations are given and exemplified by means of examples. One of these examples is the adjustment of the angles of a quadrilateral taken from the Survey of the Great Lakes of North America, executed by the United States engineers; three methods of solution are given, one of them being that adopted by the United States engineers.

The author remarks very truly that it is a waste of time applying the rigid methods of adjustment to tertiary or even to secondary triangulation, and he proposes a method of successive approximations by first adjusting the angles at each station for the local conditions, and then using these adjusted values for the further adjustment in connection with the side and angle equations of the net. It may be mentioned that the reduction of the secondary triangulation of Great Britain, now being carried out, is effected by a graphic method applied after the angles have been locally adjusted: this method is found to give excellent results with far less labour than even an approximate method of calculation. The criticism on the title of the work is well exemplified in the chapters on base-line measurements and on the graduation of line measurements. For instance, there is no mention of the corrections required to be made to a base-line measurement to allow for errors in alignment or of level, for the effects of temperature and for reduction to sea-level. We think that at any rate a sketch of these and other sources of error and their methods of adjustment would not have been amiss.

The adjustment of the errors of trigonometrical levelling is very fully considered, and one of the examples proposed for solution is the adjustment of the levels taken trigonometrically during the triangulation executed to determine the axis of the St. Gothard tunnel.

The following remark is, we think, worth quoting:—"Closely allied to the preceding (elimination of accidental errors) is the common idea that if we have a poor set of observations good results can be derived from them according to the method of least squares, or that if work has been coarsely done such an adjustment will bring out results of a higher grade. A seeming accuracy is obtained in this way, but it is a very misleading one. The method of least squares is no philosopher's stone; it has no power to evolve reliable results from inferior work."

An excellent feature in the work is the illustration of the text by means of examples, embracing almost every possible case that occurs in practice. Some of these examples are fully worked out, others are proposed as exercises. Most of them are derived from geodetic work carried out in the United States. In conclusion we can strongly recommend this book.

OUR BOOK SHELF

On the Higher Teaching of Agriculture. By the Rev. J. B. McClellan, M.A. (Edinburgh: T. and A. Constable, 1884.)

NOT the least among the benefits of the International Health Exhibition was the series of Conferences held in connection therewith; and of these, one of the most valuable was the Conference on Education held in August last. Dr. Armstrong's paper on science-teaching in

schools has been already noticed in NATURE (vol. xxxi. p. 19), and the paper before us, by the Principal of the Royal Agricultural College, Cirencester, is another product of the Conferences. The author looks on agriculture broadly, as extending, like the theme of the poet of the "Georgics,"

> " . . . super arvorum cultu per corumque
> Et super arboribus,"

and in a well-reasoned and well-written paper pleads for the teaching of the natural sciences, their facts, laws, methods, and applications to agriculture, to those who have the direction of agriculture in this country, or who seek fortunes in the soils of new countries. Cowley, two centuries ago, asked, "Who is there among our gentry that does not entertain a dancing-master for his children as soon as they can walk? But did ever any father provide a tutor for his son to instruct him betimes in the nature and improvements of that land which he intended to leave him?" Though this reproach is not deserved so much now as when it was written, it is still not wholly unmerited, and will so remain until those who have the possession and management of landed property shall receive some special training such as that sketched out by Mr. McClellan. This training, if fairly common, would do far more to mitigate agricultural depression than any amount of piecemeal legislation. The paper is a useful addendum to Mr. Jenkins's recent report on agricultural education, and it may be commended to the attention of landowners and others connected with agriculture.

The Text of Euclid's Geometry. Book I., uniformly and systematically arranged. With a discussion of Euclid's application of logical principles, copious notes, exercises, and a figure-book. By J. Dallin Paul, R.N. (Cambridge: Deighton, Bell, and Co., 1884.)

THIS is a "prodigious" work of 182 pages demy 8vo, printed on excellent paper, with clearly-drawn figures, devoted to the "painful" elucidation of all the difficulties to be found in the first book of Euclid's Geometry, with such other matter as hath been adumbrated in the above-cited title-page. The road may be an easy one to walk in, all stones of offence being carefully put on one side or so rearranged that the wayfarer may not stumble as he saunters along it, but it certainly is a long road. The tendency of modern agitation a few years ago was to condense our text-books with a view to get up geometry in the minimum of time, but experience has taught us that in the majority of cases junior boys are very tender-footed, and cannot be driven along the geometrical path, and so there has been a reversion to the "grand old" book with many an aid to lure the young into paths not naturally attractive to them. We do not find fault with these attempts—we have recently noticed in these columns two admirable editions of the "Elements,"—but Mr. Paul has taken, we think, an extreme course: at some perhaps not distant date, if this sort of editing is catching, we shall have a similarly got-up work devoted to Euclid's treatment of isosceles triangles with a preliminary chapter on an axiom.

Our author has had so much to do with Euclid that his views of life have possibly got to be Euclid-tinted, and he sees nothing but Euclid! It would be no wonder, for his own words are, in deprecation of the presumption of adding another edition to the many that have gone before, "having been teaching Euclid almost daily for the last twenty years to pupils who, before coming under his tuition, had learnt something of geometry from the different text-books in use during that time, he ventures to think that this experience has made manifest to him the principal advantages and disadvantages of these numerous works, and thereby enabled him to present the propositions in the form most likely to be of educational value to those who are beginning either to learn or to teach the subject." We have allowed the author to put so much in evidence that the majority of our readers may gather that this is not "just the book they wanted" for themselves, and yet may see the scope of Mr. Paul's labours.

We cannot commend the author's action in placing the notes on the propositions in the early part of the book; experience has shown him that when placed in their usual position at the end they are passed by, but their actual position here offends *our* eye, and will not, we fancy, secure the writer's object. We regret that the writer has spent so much time and thought to so little purpose, as we believe, for we cannot imagine who will be the public that will purchase his book, its size and price are a bar to its introduction into school use. We close with remarking that there is a good deal that may be of use to (say) a pupil-teacher, or to one who is not strong in geometry and yet has to teach young pupils; but much, if not all, of this, can be got in handier text-books. A good feature is the placing at the end the particular enunciations of the propositions with the diagrams placed in positions very different from those which they had in the text: this would enable a pupil to test his acquaintance with the subject. R. T.

Das kleine botanische Practicum für Anfänger. Von Dr. Eduard Strasburger. Mit 114 Holzschnitten. (Jena, 1884.)

A BOOK by Prof. Strasburger, entitled "Das botanische Practicum," has recently been reviewed in NATURE, and recognised as a most valuable addition to botanical literature. The same author has now produced a condensed edition of the same book under the heading given above. The more important of the facts distributed through the 600 pages of the first and larger edition are here collected into the smaller space of 250 pages, an arrangement which is obviously better suited to beginners. It was specially remarked in the review of the larger edition that the efficient study of the various types named would occupy the average student a longer time than the author of the book appeared to think. This smaller edition will obviate the difficulty by supplying the elementary student with a shorter course of study, while the larger book will no doubt be found more useful as a book of reference for more advanced students, or as providing a curriculum for those who will make botany their profession. The merits of good type and excellent illustrations are to be found in this smaller book in as high a degree as in the earlier and larger edition. F. O. B.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Dr. Koch and the Comma-Bacterium

THE article published in NATURE of December 4, setting forth Dr. Koch's well-known theories with regard to the connection of a comma-shaped micro-organism with cholera, serves very efficiently as the text for one who desires to point out the deficiencies in Dr. Koch's observations and reasonings on this subject. The article is the most favourable statement which can be made on the side of those who accept Dr. Koch's conclusions, and is to a certain extent not quite fair to his opponents, since his original statements are not clearly separated from the subsequent statements which he has made in reply to criticisms.

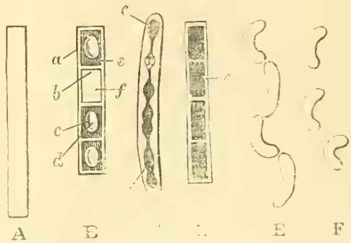
In opposing Dr. Koch's conclusions, it is desirable at the very first to state clearly that those who accept them appear to labour under two important misconceptions, the first being that Dr. Koch is, and has been for a long time, acquainted with *every* form (and the complete history of every form) of Schizomycetes or Bacteria existing, whether in the healthy body or in disease,

or in non-parasitic conditions; the second being that no one, with the exception of Dr. Koch and one or two of his pupils, has any real first-hand knowledge of Bacteria which is of any moment. It is hardly necessary to insist in the pages of a scientific journal upon the fact that these really are misconceptions. Our knowledge of the Bacteria is in its infancy—and Dr. Koch's knowledge of them is no more than that which an industrious worker may be expected to have gained in the course of very special observations in regard to a limited class of these organisms (the pathogenic class) extending over a few years. On the other hand, the study of Bacteria has been prosecuted from three separate points of view during the past fifteen years by a number of observers, who may be grouped according to their point of view as the botanists, the chemists, and the pathologists. It is undeniably the fact that neither the chemists nor the pathologists have given much heed to the work of the botanists, and that the results attained by the three groups of workers have not been brought into harmony. To the medical world the special investigations of the pathologists alone are familiar, and undue weight has been given on the one hand to generalisations which ignore the more widely-based conclusions of the botanists, and on the other hand to the introduction into the pathological arena of methods of study which are not new or original, but have been borrowed from the botanists, whose opinions are nevertheless ignored or dismissed with little consideration. As examples of these tendencies I may quote the reiterated assertion by Dr. Koch, and the pathological school, of the conclusion (upon which they base many very momentous arguments) that the forms and the activities of Bacteria are absolutely fixed and limited—that micrococci only produce micrococci, bacilli only bacilli, spirilla only spirilla, and that none of these forms vary from generation to generation, or can be produced from another of these forms, and that a micro-organism producing a particular disease or a particular ferment cannot in the course of generations lose the property of producing that disease or that ferment, and *vice versâ* that one not having such properties cannot, in the course of human experience, acquire them. This axiom of the pathologists as to fixity of form and property, is entirely opposed to the conclusions of the botanists, who reason from a much larger area of observation. Such authorities as Nägeli, Cienkowski, and de Bary are amongst those who maintain, in opposition to the pathological specialists, that wide range of form and wide range of physiological activity are possible in one species or "race" of Bacteria. To this subject I propose to revert in detail, on a subsequent occasion. As an example of the borrowing of methods by pathologists from botanists, I may quote the fact that it is customary in the writings of pathologists to attribute the gelatine method of cultivation to Dr. Koch, and to attach some additional weight to his conclusions on the ground that he has originated this and other ingenious methods of research. As a matter of fact, the gelatine method of cultivation, which is only a modification of the potato-slice method, is due to the botanist Brefeld (as acknowledged by Koch himself).

Whilst it appears that there has not been on the part of the pathologists engaged in the investigation of Bacteria such an acquaintance with, and appreciation of, the work of the botanists as would be conducive to sound conclusions, it is true that the chemists also have frequently failed in the same way. Much of the work of M. Pasteur on Bacteria is difficult, if not impossible, to verify or to use in any way, on account of the fact that he has not, in prosecuting his studies on these minute plants, made correct use of the conceptions and terminology of the botanists, and has on the other hand used that terminology erroneously and in a special sense.

Dr. Koch has given a very remarkable proof of the isolation of his knowledge and work from that of the botanists (among whom without question the most trustworthy conclusions in this department of knowledge are likely to be found) by his use of the term "spore" in his description of the tubercle-bacillus discovered by him. The "spore" of a bacillus, as shown more especially by the minute studies of the botanist Oscar Brefeld, is a very special structure formed within the filament of the bacillus by a modification of a *part* of its protoplasm, and provided with its own special capsule. Koch actually describes the whole of the constituent protoplasm of a tubercle-bacillus which has a moniliform arrangement as a series of "spores," although it is quite clear that there is nothing in common between the arrangement of the entire protoplasm of a bacillus in the form of a string of micrococci and the periodic and special elaboration of the spores of the hay and anthrax bacilli. The so-called "spores" of the tubercle-bacillus are spores only in the sense that all segments of bacteria which can be detached and multiply are spores (Arthrosporeæ of de Bary) and do not justify the distinction which Koch makes when he states that the tubercle-bacillus is characterised by producing spores, whilst stating that spirilla, such as the spirillum of relapsing fever (which breaks up into segments capable of growth), do not produce spores.

Bearing in mind these facts as to the attitude of different schools of bacteriologists, let us examine the claim put forward



A, Outline of the bacillus of glanders (which Koch says resembles the comma F). B, Diagram of *Bacillus subtilis* of hay infusion during sporulation; *a*, sheath of the bacillus; *b*, transverse septum; *c*, coat of a spore; *d*, content of a spore; *e*, protoplasm surrounding the spore, which disappears entirely when the latter is fully formed; *f*, empty or sterile segment. C, Tubercle bacillus; the protoplasm is arranged in moniliform masses (*e*), which are erroneously called "spores" by Koch. D, Diagram of hay bacillus in vegetative state; the protoplasm is arranged in block-like masses (*e*), comparable to the moniliform masses of C. E, Spirillum dividing into commas. F, Commas (stated by Koch to be identical in form with the glanders bacillus, fig. A).

by Dr. Koch, and on behalf of Dr. Koch, by the writer in NATURE of December 4, p. 97, to have discovered that a certain comma-shaped bacterium is the cause of cholera. The writer in NATURE gives a summary of the various peculiarities of growth, form, and properties which Dr. Koch states he observed to be characteristic of a micro-organism occurring in the intestine of persons dead of cholera. He then observes: "Micro-organisms presenting all these characteristics are the bacilli described by Koch; organisms presenting only some of the characteristics, such as microscopical appearance, but differing in other points, are not Koch's comma-bacilli." To this conclusion, it is quite impossible in our present state of knowledge to assent. Its acceptance by the writer of December 4 renders it improbable that he will ever be convinced that Dr. Koch has formed an erroneous conclusion. The pretension put forward on behalf of Dr. Koch amounts to this, viz., that he has ascertained all the properties of this organism, that he cannot possibly have made any mistake, and that it is more probable that this organism has, since Dr. Koch left India, disappeared from existence, and been replaced by another very much like it, but not quite the same, than that any subsequent observer should be able to correct the hurried observations made by Dr. Koch when he was there. Such a pretension, were it advanced in regard to an animal or plant belonging to a group of exceedingly well-defined and highly-organised species would be unreasonable, but when put forward in relation to a representative of a group consisting of such minute, unstable, protean, and ill-understood species as are the Bacteria, must lead us to question altogether the impartiality and critical faculty of those who make it.

Admitting, however, for a moment that Dr. Koch's comma-bacillus is as peculiar as he supposes, admitting, as Dr. Koch originally implied by his silence as to the existence of other comma-shaped bacteria, that it is utterly unlike anything at present known in shape as well as in its action on gelatine, Dr. Koch has not proved or even rendered it greatly probable that this comma-bacillus is the cause of cholera, even when we accept his statement that "he has always found the comma-bacilli constantly accompanying cholera, and that he has never found them elsewhere." In the first place, it is quite certain both from Dr. Koch's reports and from the observations of others, that cases of cholera occur in which these commas are not abundant, in fact are insignificant in quantity; and in

the second place, great as has been Dr. Koch's activity in the study of Bacteria, the fact that he and others with whom he is in relation have not found the "comma-bacilli" elsewhere does not render it at all improbable that other observers might find them elsewhere. This fallacy, viz., as to the perfection of Dr. Koch's knowledge of all possible forms and modes of occurrence of Bacteria, I have already pointed out above.

On the supposition that these comma-bacilli *never* occur except in the choleraic process it is of course impossible to maintain (see the article in NATURE of December 4, section (7), p. 98) that the choleraic process merely favours the growth of the commas. But Dr. Koch admits that they occur and flourish outside the human body, in immediate connection with cholera dejecta; also that, when artificially cultivated, they flourish on substances not derived from the human intestine. What proof is there that they do not naturally continue so to flourish? Dr. Koch offers none—he merely tells us that he has failed to show that they do. It is not at all impossible, on Dr. Koch's own showing, that they do—and if they do, what becomes of the argument as to the impossibility of their introduction from external non-choleraic conditions into the human body?

The suggestion is also considered by Koch (and is cited in the section of the article already mentioned) that, "as a result of the disease (cholera), conditions arise which cause the transformation of some ordinary bacterium into comma-bacilli." But, say Koch and his English disciple, there is no evidence of such rapid transformation of one form of bacterium into another. Here we meet with the special axiom of the pathologists to which I have already referred. The opinion of those who are entitled to the very greatest consideration, namely, the botanists Nägeli, Cienkowski, and de Bary, is that there IS evidence of such rapid transformation of one form of bacterium into another. Without going further than the case cited by the writer in NATURE as "merely" an alteration in pathogenic action, we have the instance of the attenuation of the virulence of anthrax bacilli, and we have also the case of the complete change of form of that same bacillus into nostocoid chains of spherical elements when cultivated on pork broth as shown by Klein. These two cases are by no means isolated ones (see my own researches on *Bacterium rubescens*, and also those of Zopf), but were they so they would be sufficient to establish the possibility of such changes in other Bacteria and to destroy the argument based on the assumption that such change is impossible.

The "only conclusion which remains" (see paragraph (*c*), section (7), in the article referred to) is therefore NOT that these bacilli and the cholera processes stand in the relation to each other that the commas are cause and the cholera effect. On the contrary, the only conclusion which remains is that WE DO NOT KNOW whether the commas although not detected by Koch may not be present in some parts of the healthy body, or flourishing outside it on organic matter, or may be the result of the transformation of some other bacterium, or may be the cause of cholera.

And the only way in which that ignorance can be removed has been very clearly recognised by Dr. Koch and all other recent writers, previous to the attempt made by Koch in 1884 to persuade the medical and scientific world that he had discovered the cause of cholera. The obscurity and uncertainty surrounding the Bacteria is such that no value can be attached to any asserted connection of a micro-organism with a disease as the cause of that disease, which is not based upon the experimental production of the disease by the inoculation into healthy animals of "pure cultures" of the suspected micro-organism. Dr. Koch's earlier statements on this subject are so precise and apt that I cannot do better than quote them here. He says in a pamphlet published in 1882, entitled "Ueber die Milzbrandimpfung":—

"The position which I take up is briefly as follows:—It is not yet proved that all infectious diseases are caused by parasitic micro-organisms, and consequently in each particular disease the proof of the parasitic character of the disease must be furnished. The first step towards this proof consists in the careful investigation of all those parts of the body affected by the disease, in order to establish the presence of the parasites, their distribution in the diseased organs, and their relation to the tissues of the body. . . . It is not until a thorough knowledge has been obtained in this way as to whether micro-organisms are present in the diseased parts, at what points they are present in perfect purity—whether, for instance, in the lungs, spleen, heart's blood, or elsewhere—that the attempt can be made to obtain the proof that these micro-organisms are of a pathogenic nature, and that they are more especially the cause of the disease in question. With this object in view, they must be isolated by means of 'pure cultivation,' and when they have been freed in this manner from all particles of the diseased body originally adhering to them they must be introduced by inoculation into the same species of animal in which the disease was observed, or, if that should not be possible, into animals in which the disease in question is known to occur with unmistakable symptoms. . . . An example is afforded by the disease known in man as erysipelas. It has been known for a long time that in this disease micrococci constantly are found in the lymph-vessels of the skin. *But by this knowledge it certainly was not proved that the micrococci are the cause of erysipelas.* Now, however, that Fehleisen has recently succeeded by excision of portions of skin from erysipelas patients (with every precaution against contamination by other bacteria which might be accidentally present on the skin) in rearing these micrococci in 'pure cultivations,' and in producing typical erysipelas by inoculating the human subject with these isolated micrococci, there can no longer be any doubt that the micrococci are, in fact, the cause of erysipelas, and that the latter is to be regarded as a parasitic disease."

This is the kind of proof which we require in the case of the comma-bacillus, and its supposed causal relationship to cholera. Dr. Koch has not succeeded in obtaining that proof. He has tried, and has failed, to produce cholera by inoculation of "pure cultivations" of his "comma." Cholera, at present, is not known as a disease in animals. Nevertheless, Dr. Koch has urgently and persistently declared that he considers it to be proved that the comma-bacillus is the cause of cholera! After repeated and public declarations of this conclusion, he is now making experiments by introducing his "comma-bacillus," not through the mouth, but by fistulæ into the intestine of rodents. Those who know the history of experiments on the production of cholera in mice and other rodents will not be convinced, even should Dr. Koch succeed in producing choleraic symptoms in this manner, since the readiness with which cholera-like processes are induced in these animals by abnormal conditions is such as to render them unfit subjects for these researches.

II. We may now revert to some of the statements made by Dr. Koch, which in the preceding remarks we have accepted without criticism. Even when this method is pursued, we find Dr. Koch's conclusions unwarrantable; they will appear still more so when we examine his position in detail. The writer of the article in NATURE of December 4 has omitted to notice a very important charge brought by Dr. Lewis against Dr. Koch, after the publication of Dr. Koch's address to the Medical Conference at Berlin in last August. Dr. Koch, also, has remained entirely silent in regard to this matter. It would be a very important thing if he would even now frankly reply to it. Dr. Koch and his defender assert that the "comma-bacilli" were found by Dr. Koch in cholera cases in Egypt, and also in specimens of intestine sent to him from India previous to his going there. Dr. Timothy Lewis, on the other hand, asserts that Dr. Koch had *not* recognised the "comma-bacillus" previously to his visit to India, and that in Egypt Dr. Koch attributed the causing of cholera to a totally different organism from that which he put forward after his arrival in India, and that, although he had thus shifted his ground, Dr. Koch did not admit at the time, and has not since admitted, that he was at one time convinced that cholera was caused by one organism, and a few months after was convinced that it was caused by another.

This charge is of importance for two reasons. If true, it must tend to lessen the confidence reposed by some in Dr. Koch's conclusions; and, secondly, it must also lessen our belief in the candour with which he states all the circumstances attending his observations and inferences.

The following quotations from the official reports sent home at intervals by Dr. Koch, coupled with the fact that he has not replied to Dr. Lewis on this point, though he has replied to him on other points, seems to leave little room for doubt that Dr. Lewis is perfectly correct in the very grave charge which he has brought against Dr. Koch.

In his report from Alexandria, September 17, 1883, Dr. Koch says:—"These bacteria are rod-shaped, and belong accordingly to the genus bacillus; they resemble most nearly in size and form the bacilli found in glanders" (which are straight: see woodcut, fig. A). In his report from Calcutta, dated January 9, 1884, he says:—"The microscopic examination demonstrated the presence of the same bacilli in the cholera intestine as had been found in Egypt." In a further report, dated February 2,

1884, we at last get the following remarkable statement:—"The bacilli are not quite rectilinear, like other bacilli, but slightly curved, like a comma. The curvature is sometimes sufficient to give the bacillus a semicircular form" (see woodcut, fig. F).

I think that it is abundantly clear that the organism selected by Dr. Koch in Egypt as the cause of cholera is not the same organism as that which he selected when in India, and that, although he is aware of that fact, he has not explicitly stated it, but has on the contrary (as does the writer in NATURE) endeavoured to give the impression that they are the same organism.

A further point of great importance as affecting the validity of Dr. Koch's theories, with regard to the connection of what he calls the comma-bacillus with cholera, is the statement of Dr. Lewis which is abundantly confirmed, and is not disputed by Koch, viz. that comma-bacilli, indistinguishable in appearance from those occurring in cholera cases, are quite common in the mouths of healthy persons. There is no doubt whatever that this is the case, although no record of the fact is to be found in any published treatise or paper on Bacteria, and that it was not commonly known to bacteriologists previously to Dr. Lewis' announcement of it in last September. The writer of the article in NATURE of December 4 hardly gives full effect to the importance of this point, since he cites Dr. Koch's reply to Dr. Lewis at the same time that he records Dr. Koch's earlier statements. Setting aside for the moment Dr. Koch's reply to Dr. Lewis, let us examine Dr. Koch's statements bearing on this subject, at the time when he announced his supposed discovery of the cause of cholera. He wrote from India that the organisms which he identified as the cause of cholera were of *peculiar* form, and "on account of its peculiar form, I have given to it the name of comma-bacillus." Throughout his subsequent writings, previous to the publication of Dr. Lewis's report by the Army Medical Department, Dr. Koch speaks of his cholera-organism as *the* comma-bacillus. He does not mention that any micro-organism similar to it in form is known to him. Had he been acquainted with one commonly occurring in the mouth, he would certainly have said, "The cholera comma is very like one occurring in the mouth, but differs in such and such ways." So far from this, he expressly says that no similar organism occurs in the human body, and states that he has failed to find an organism like the comma-bacillus in (amongst other places) the human mouth. No subsequent statement (after Lewis's publication) can affect the evidence which we have here that Dr. Koch was not acquainted with the "comma" which occurs in the human mouth.

After Dr. Lewis had shown that a "comma-bacillus" indistinguishable from Koch's "comma-bacillus" occurs in the healthy human mouth, and that accordingly—if we may suppose, from their identity of form and close association, that the two organisms are identical in every respect—the fundamental proposition of Koch as to the exclusive association of his comma-bacillus with cholera utterly breaks down, Dr. Koch replied as follows—(1) that the occurrence of a comma-bacillus in the mouth had long been familiar to bacteriologists (he did not say, it is to be noted, that it had long been familiar to him); and (2) that this comma-bacillus of the mouth will not grow upon neutralised cultivating-gelatine, whereas that from the intestine will, and that accordingly there is no ground for regarding them as identical species.

It seems to me in the highest degree improbable that Dr. Koch was acquainted with the mouth-comma when he published his conclusions as to the cause of cholera. If he was acquainted with it, it is undeniable that he committed a very grave fault in not drawing attention to it, and pointing out then and there the differences presented by cultures of the two commas. I have fairly conclusive evidence before me of the fact that Dr. Koch was not acquainted with the comma-bacillus of the mouth two years ago, when he published his large report and coloured plates on the tubercle-bacillus. In one of the drawings in that work he gives a delineation of the chief forms of micro-organisms occurring in the mouth, in order as he says to enable other observers to guard themselves against any confusion of the tubercle-bacillus with the micro organisms which are normally present in sputa. *No comma-like organism is figured in that drawing or mentioned by Dr. Koch.*

As to the cultures of the "comma" from cholera intestines on the one hand, and from the healthy mouth on the other, differing in respect of their properties or their sensitiveness to conditions of alkalinity and neutrality, I venture to say that, *taking into consideration the whole history of the case*, it is not sufficient for Dr. Koch to tell us in an abrupt way that such differences exist. There is no reason to accept as final and perfect Dr. Koch's account of the characters of the comma associated with cholera, and I should greatly prefer to have the comparison of the conditions of growth of the commas from these two sources made by some one who is not, as Dr. Koch must unfortunately be, so very seriously biased in one direction.

I think there is some reason to expect that we shall hear from Dr. Klein as to the result of his impartial experiments, now being carried on in Calcutta, that the comma which occurs in the healthy mouth behaves in precisely the same way under cultivation, and is in fact as in appearance the same organism as the comma which occurs in the intestines of cholera patients.

Lastly, I may record a protest against Dr. Koch's extraordinary term "comma-bacillus." I have already pointed out that Dr. Koch uses botanical terminology loosely. The word "bacillus" has been by common consent restricted to the description of such rod-like forms as Koch first associated with cholera as the result of his Egyptian work. To prefix the word "comma" to this, was perhaps a method of avoiding unpalatable explanations. At the same time it is utterly inconsistent with the sense of the words. What Koch calls "comma-bacilli" may for convenience be termed "commas." They are well known to botanists as the segments of a spirillum (see woodcut, fig. E), the result of the breaking up of a spirillum into little pieces, one corresponding to each turn of the spire. They have been clearly figured and their nature recognised by Zopf. The "commas" of the human mouth and intestine are undoubtedly related to a spirillum which is frequently found in association with them, and would not have caused any astonishment or been stigmatised as "peculiar" in form by an observer who had that adequate knowledge of the natural history of the Schizomycetes in general which Dr. Koch has in many ways shown that he does not possess.

E. RAY LANKESTER

[We desire merely to make one remark with regard to the foregoing letter. The article referred to was prepared at the request of the Editor with the view of putting before the scientific public a fair and complete statement of Dr. Koch's case. The writer of the article requests us to state that he did not, except in the last paragraph, give any views of his own, and holds himself perfectly neutral in the matter, his mind not being at all made up on the subject.—ED.]

On the Distribution of Honey-Glands in Pitchered Insectivorous Plants

THE four genera of pitchered insectivorous plants at present in general cultivation are Nepenthes, Sarracenia, Darlingtonia, and Cephalotus. Attention was drawn to the minute structure and physiological action of the first three of these by Sir J. Hooker in his celebrated presidential address to the British Association in 1874, while the structure and morphology of the last was treated of by my master, Prof. Dickson (*Journal of Botany*, 1878, 1881). Both observers pointed out an *attractive surface* studded with honey-glands, which constituted the lid part, a *conducting surface*, either of an exceedingly smooth nature (Nepenthes), or beset with small downward-directed hairs (Sarracenia, Darlingtonia, Cephalotus), and in most cases a *glandular surface* (Nepenthes, *S. purpurea*, and Cephalotus), the secretion from which directly or indirectly assisted in digestion of animal products. In Sarracenia and Darlingtonia there was found in addition a *detentive surface*, covered with long deflected hairs.

A year ago Prof. Dickson further drew attention to a set of magnificent attractive glands along the free edge of the corrugated rim in Nepenthes, which he named "marginal glands."

My attention has recently been directed to all the genera, and I propose stating here the main results. A detailed account of the comparative results obtained by examination of the different species in the young and adult condition will shortly be presented to the Royal Society of Edinburgh.

Nepenthes.—Examining a pitcher of Veitch's beautiful hybrid, *N. Mastersiana*, I observed on its outer surface what seemed to be the small openings of honey-glands. When microscopically examined, they were found exactly to resemble those on the inner lid surface, except that the gland fossa was deeply hollowed out, and opened externally by a small orifice, while its inner surface was clothed to within a short distance of the orifice

by the gland tissue, very much as in sphæriaceous fungi the cavity of the perithecium is lined by asci. But even in this they agreed with the lid glands noticed by Dickson in *N. lævis*, and termed by him "perithecioid." Careful study of the outer lid surface revealed a few similar glands. On comparison of the species and hybrids grown in the Royal Botanic Garden, Edinburgh, a like condition was found to occur in all. The presence of these on the outer pitcher surface of *N. ampullaria* is interesting, since in it the lid is rudimentary, directed back, and destitute of glands on its inner surface.

At Prof. Dickson's suggestion I then examined the expanded lamina, and was agreeably surprised to find that glands were scattered rather sparingly over its upper, but pretty abundantly over its under, surface, especially near its junction with the stem. The tendril intervening between the lamina and pitcher also possessed them, and in some cases they were of very large size. Passing to the stem, it was found that some species had them very sparingly, others in considerable number, but while resembling those on the leaf externally, they were sunk much deeper in the tissue of the cellular layer, and strikingly reminded one of a simple animal gland.

After a comparative study of the different species I was induced to look at the sepals, as our garden curator, Mr. Lindsay, had mentioned to me that a very copious secretion of nectar took place in flowering. A complete pavement of glands the same in size and appearance as those on the inner lid surface of the pitcher, was spread over the upper epidermis of each. In Hooker's elaborate monograph of the genus ("De Cand. Prod.," vol. xvii.) these are mentioned, though their complete resemblance to the latter is not indicated. A few large "peritheicoid" glands may also be seen on the lower epidermis, and in flowers of *N. bicalcarata* (for opportunity of examining which I am indebted to Mr. Courtauld of Braintree), these attain relatively a gigantic size.

We see, therefore, that in Nepenthes, with its diœcious flowers, the same structure, which by their secretion attract insects for aiding in fertilisation, also lure them to the pitcher, so that their dead bodies may help in the nutrition of the plant.

Sarracenia.—Mellichamp pointed out (*Gardener's Chronicle*, 1874) that honey-glands are present not only on the lid, but also on the external projecting wing of the pitcher. I find, however, that, as in the last genus, they are diffused over the whole outer surface, including the lid; further, that in some of the species (*S. variolaris* and *S. rubra*) there are external upward directed hairs, as in some of the Nepenthes. On the outer surface of the three bracteoles and of the sepals the glands are likewise numerous, and will undoubtedly be insect attractors for promoting cross-fertilisation.

Darlingtonia. This genus agrees with the last, except that the glands are very simple, being one- or at most two-celled. I have not as yet examined the flower, though there can be little doubt but that in it a like condition will occur.

Cephalotus.—Prof. Dickson, in studying this genus, noticed glands not only on the lid and outer pitcher surface, but even on the ordinary foliage leaves. I therefore required to deal only with the flowers. Scattered among the "encapsulating" hairs on the peduncle, bracts, and six sepals, were many glands identical with those of the leaves, though rather smaller; but further, the peculiar glandular processes intervening between the stamens and carpels seem to be the same mounted on cellular outgrowths of the receptacle.

Nepenthes, Sarracenia, Darlingtonia, and Cephalotus are therefore found to agree fundamentally in their morphological arrangements for physiological purposes, though referable to orders widely separated systematically.

Earthquakes in England, and their Study

As no record of the most recent earthquake shock in England has yet found a place in the pages of NATURE, perhaps I may be permitted to give the following slight details, collected from the daily papers of Lancashire and London for November 15:—

A shock of earthquake ("severe," yet causing no actual injury) was experienced at Clitheroe, and in the neighbourhood, on the evening of November 14. At about 5.10 p.m. a terrific report, resembling loud thunder, was heard, instantly followed by a strong vibration of the earth, sufficient to induce the inhabitants to run out of their houses into the streets in a terrified state.

At Low Moor, where the shock seems to have been felt most strongly, the wife of a man named Wilkinson fainted with fright. A waggoner on the road states that his two horses were nearly thrown to the ground. Much excitement prevailed throughout the borough and neighbourhood of Clitheroe, especially at Low Moor.

A lurid glare noticed in the sky at the time of the disturbance —5.10 p.m., sun set at 4.10—is mentioned in connection with the occurrence, but that appearance was, in all probability, only one of the sunset-glow effects with which we have lately become so familiar, and had nothing to do with the shock.

The circumstance that this particular part of Lancashire is much subject to earthquake disturbances, makes it specially important that no details of their occurrence be lost to science. Within the last fifty years at least six well-authenticated shocks have been recorded,—in 1835, 1843, 1868, 1871, 1873, and 1884,—and this list might easily be extended. Lancashire, indeed, may be considered as one of the chief areas of disturbance in England, and after Comrie, in Perthshire, perhaps the most important centre of seismic action in Great Britain.

While writing upon this subject, perhaps I may be allowed to offer the suggestion that, as the study of seismology is now one of such growing importance, it would be of considerable interest to many if a small space were set apart in the columns of NATURE every month, devoted specially to the record of current earthquake action, and kindred convulsions, in a scientific manner. It is my experience, as one who has for some time been engaged in collecting certain facts of these phenomena from various sources, that no sufficiently precise and complete records of the necessary facts, as may thus be readily transferred to the annals of exact science, are anywhere available. The general observations of seismic disturbance as heretofore described, are usually not only scanty in the matter of their detail, and often dressed up still with a superstitious flavouring, but also, for lack of *the right class* of observation, are too frequently merely vague and useless statements of wrong facts, generally in favour of doubtful hypotheses; and these are allowed to take the place of a well-ordered treatment of the real state of the case, upon a proper scientific basis.

The Cacao-Bug of Ceylon

THE note by Mr. Distant in your number for October 30 (p. 684) may perhaps lead its readers to think that the insect which has lately been the subject of a report to the Ceylon Government has been wrongly identified by me as *Helopeltis antonii*, Sign. As that report will, however, before this have reached England, the matter will probably have been set right. I am not an entomologist, nor have I here the opportunity of reference to Signoret's original description or to other descriptive works; but the insect is, without any doubt at all, that which is well known—too well known—in Assam and in Java as *Helopeltis*. In the former country it is the destructive tea-bug or "mosquito-blight,"[1] and in the latter it is the notorious pest of the cinchona plantations.

As to the fragments which reached Mr. Distant, they were apparently insufficient for identification, further than with the family *Reduviidæ*. The cacao-tree harbours a host of Hemiptera, and planters are very apt to confound the innocent with the guilty. Its only formidable enemy in this order of insects, however, so far as I have seen, is the *Helopeltis*.

Royal Botanic Garden, Peradeniya, Ceylon, November 21

The "Messenger of Mathematics"

I THINK it is right that attention should be publicly directed to the exceedingly irregular appearance of the *Messenger of Mathematics*. In the case of a magazine of its size and character there is no reason whatever why it should not be published on the first of each month. The "heavy" mathematical journals may be permitted to turn up when their editors please; but the case of a *monthly* meant to foster a taste for mathematical investigation among junior mathematicians is entirely different; indeed, the good such a magazine is calculated to do is almost nullified by irregular publication. The *Messenger* is always

[1] Since my report was written, Mr. Wood-Mason's short treatise on the tea-bug has reached us here.

more or less irregular: just now, however, it is drawing so long a breath that one fears that its last message has been carried. We are now in the middle of December and the *October* number has not yet been heard of! ANGELUS

The Pronunciation of Chinese Names

SOMEWHAT after date, I beg to return to the subject of Anglo- and Franco-Chinese orthography, referred to in NATURE, vol. xxx. p. 592. In a short paper of mine published in the *Proceedings* of the Royal Geographical Society, vol. xxii. No. 6, 1877, I alluded to the desirability of a uniform or fixed "Roman equivalent" for Chinese characters standing for names of places, &c. I inclose a copy of this paper for insertion if desirable. To my mind the Italian vowels, &c., come nearest to the sounds of the Chinese characters. *Tung-King*, meaning "Eastern Capital," is the usually accepted form of *Tonquin*, or *Ton-Kin*, the terminal *g* being but slightly sounded. *Shang-hai*, the "Upper Sea," or the place "of going up to the sea," should be pronounced with the *g*, and is so spoken (Shanghai) by English and American authorities. Dr. Wells Williams has, I believe, in manuscript a standard Chinese Gazetteer of the World, in which all proper names likely to be used in telegraphy, newspapers, &c., are smoothly transliterated into Chinese characters. For translations from Chinese it is very necessary to adopt some such plan as Dr. Hunter has suggested for Indian names. Although his plan has come too late into the field to induce people to spell Calcutta as Kolkata, this is hardly the case as yet with Chinese names. The old native names of places should always be literally preserved. How much more beautiful is the old Franco-Indian name Stadaconda than Quebec for the scene of the death of Wolfe! I should be glad to co-operate or correspond with any interested in this matter, so prominent and important at the present juncture. F. PORTER SMITH

Hillworth House, Shepton Mallet, December 12

EXPLORATIONS IN ICELAND[1]

THE LAVA DESERT OF ÓDÁÐAHRAUN

III.

THE second part of my programme included the exploration of the western and southern portions of the Ódáðahraun Desert. In this journey I spent a fortnight during the latter half of August, a thoroughly rough and arduous time, on account of the very unsettled weather alternating between cold and rain, tempestuous gales, snowstorms, and sand-hurricanes. My journey extended to 240 English miles, but only two oases of grass were discovered the whole way. Along the skirts of Vatnajökul, throughout the whole extent of the lavas and sand plateaus which form the northern fringe or border intersecting it from Ódáðahraun, not one single blade of grass, nay, not even signs of mosses or lichens, are anywhere discoverable, hence we were obliged to provide ourselves with fodder for the horses in the shape of hay, oats, and maize dough.

The results of the journey are in every way as good as, under the circumstances, I could have anticipated. Now at last the whole of Ódáðahraun, with its surrounding wildernesses, has been explored. The weather was often enough sufficiently clear and fair to give me an opportunity to note all that required surveying The few who have travelled over various parts of these deserts before me have seen next to nothing, on account of bad weather. Ódáðahraun, as stated in a former letter, is the largest lava-desert not only in Iceland, but in all Europe; the main portion of it has been formed by volcanic activity in Iceland in prehistoric times; but since the discovery of the island, even down to our own day, the region has witnessed a succession of eruptions. The various lava flats form one plateau, the bounds of which are determined on the east by Jökulsá in Axarfjörd, south by Vatnajökul, west by Skjálfandafljót, north by Mývatn. At its southern extremity it rises to 3200, at its northern to from 1400 to 1500, feet above the level of the sea. Altogether I took there about two hundred barometric and trigonometrical elevations and surveys. The separate lava-flats are due to about twenty separate volcanoes, honeycombed by hundreds of craters. Several of the separate lavas are, to the extent of many tens of square miles, one unbroken flat lava-field as it were; others, again, all torn up and disrupted, in some cases almost, in others entirely, impassable. The substratum of Ódáðahraun is palagonite-tuff and breccia, over the top of which is spread the doleritic lava, the origin of which dates from before the Glacial period. Above all the modern lavas have flowed. All the mountains that tower above the lava consist of palagonite breccia; along their roots and spurs are frequently found rows of craters, as well as those shield-fashioned volcanoes from which the lavas have welled out. The largest volcanoes have been built up entirely by lava-floods, which have flowed successively over each other, so as to form enormous convexities presenting an equal inclination to every side, but so slight as to amount to only a few degrees. This kind of volcano, which in the north country is generally designated by the name of Dyngja, reaches in Iceland nowhere such dimensions as in Ódáðahraun, as for instance Kollótta-Dyngja, Trölladyngja, Kerlingar-Dyngja, Ketil-Dyngja. In some places many rows of craters are ranged together along rifts from north-east to south-west, as on Reykjanes, and in Dyngjufjöll, where the craters around Askja and along the slopes of the mountains are practically innumerable. In Ódáðahraun proper hardly any water is found; rain sinks through the lava, and emerges again from under its edges in many small rivers and springs. The southernmost portion of Ódáðahraun has already been buried under glacial mud and sand from Vatnajökul, incessantly poured over its edge towards the north by innumerable glacial rivulets, that mostly vanish into the underlying sands and the lavas over which they are spread. Some of the larger streams, however, find their way eastward to Jökulsá in Axarfjörd, and a few into Skjálfandafljót. In consequence of the elevation of Ódáðahraun above the level of the sea, and of its waterless condition, it is a region almost barren of vegetation. On the drift-sand a few tufts of *Elymus arenarius* or stray specimens of *Statice armeria* and *Cerastium alpinum* may be found. Round the skirts of Ódáðahraun, where the water wells forth, a good deal of vegetation shows in some places, especially along the western fringes, in the valleys of Skjálfandafljót, where summer-pastures form the sheep-walks of the inhabitants of Bárðardal. On the eastern side of Ódáðahraun there are only two oases—Herðubreiðarlindir and Hvannalindir, and here the vegetation is confined to the banks of springs, its most distinguishing feature being the *Angelica archangelica*, which grows in small clusters or bushes everywhere along the banks of the brooks. There occur likewise some species of the slighter kinds of willow, such as *Salix glauca*, *S. phyllicifolia*, *S. herbacea*, as well as a few species of heather. Over the watered shingle-flats about Herðubreiðarlindir there are spread in parts red carpets of the lovely French willow-herb (*Epilobium angustifolium*). Insect life is very poorly represented, hardly anything being visible, save a few *Diptera*. To the south of Ódáðahraun not a plot of grass is to be seen, except at Gæsavötn, in Vonarskarð, where the vegetation is of the scantiest kind, comprising indeed little more than the *Salix herbacea*. Along glacial streams no sign of vegetation is ever apparent here; what little occurs grows along fresh-water springs.

It might be imagined that such a volcanic region as Ódáðahraun would be rich in hot springs, solfataras, &c. But such is not the case. The main portion of the lava is now so old, that all such volcanic phenomena seem to have died out. Of warm springs only two may be said to be still in existence, both on the western side of the lava; yet they are only lukewarm (respectively $33\frac{1}{2}°$ and $35\frac{1}{2}°$ C.) About Gæsavötn such springs obviously once

[1] Continued from vol. xxx. p. 585.

existed, but they have now almost entirely vanished (their temperature having sunk to from 5° to 7° C). Dyngjufjöll, especially the valley of Askja, are the only localities in these regions, where volcanic manifestations of this character are now to be seen; and there hot springs, clay-pits, sulphur-mines, and fumaroles of every kind are well developed. But these appearances are to be connected with an enormous eruption which occurred as late as 1875. Throughout the whole of Ódáðahraun I have come upon no traces of subterranean heat, except at the places here mentioned. About the peninsula of Reykjanes which I explored last year, many more signs of activity were found, which seems to show that in that locality the volcanic disturbances are to be referred to a later period than those of Ódáðahraun.

The northern edge of Vatnajökul has never been examined before. In my journey I was enabled to take the various elevations of this glacier, and found that at its western extremity, in the neighbourhood of Vonarskarð, it rises to its greatest height, over 6000 feet. East of this point it becomes lower, until it rises again about Kverkfjoll, where an upheaval is perceptible right across it from north to south. From the hollow, or lowest point, the largest glacier in Iceland has taken its course. It is important that this glacier should be carefully examined, but its exploration would require a long time, for it is almost impossible to make a lengthened stay here, on account of the utter barrenness of the region, and the roughness of the weather.

In this journey I succeeded in solving the geographical riddle, which of the many rivers of Iceland is the longest. It has hitherto been assumed that Jokulsá in Axarfjörd was the longest, 100 English miles; and that next to it came Þjórsá, 96 miles long; but I have now ascertained that Þjórsá is by far the longest river in Iceland, its course being about 120 miles, while Jökulsá is only 95. Hitherto, also, it has been supposed that the sources of Jökulsá were situated in the spurs of Kistufell; they are really twenty miles further to the east, under the western slopes of Kverkfjöll. The sources of Þjórsá are situated in the north-westerly portion of Sprengisandr, to the north-west of Fjórðungsalda. Þjórsá, too, carries a greater volume of water than Jökulsá. On a July day the latter carries, midway between its source and its mouth (viz. at Grímsstaðir) 14,500 cubic feet of water per second, but Þjórsá at the proportionate point (at Þjórsárholt) carries 17,600 cubic feet in the same space of time.

Akreyri, September 7 TH. THORODDSEN

AMERICAN SUMMER ZOOLOGICAL STATIONS

IN the United States there has been during the past ten years a great increase in the advantages for the study of zoology. Not only has this increase been manifested in the colleges, but also by the facilities for summer study at the sea-shore. At present we have on the Atlantic coast five stations where there are facilities for students to carry on investigations. These laboratories are of two kinds—one where only the advanced student is allowed to study, the other in which any one manifesting a sufficient interest in Nature may be allowed a chance to work upon the marine animals; these latter are themselves divisible into two classes—one in which regular instruction is given, and the other where the student is supposed to study for himself under the direction of an efficient instructor.

The laboratory at Beaufort, North Carolina, connected with Johns Hopkins University, is intended as a place where students of the University, and somewhat advanced students from other colleges, can spend the summer in advanced work. It has attained for itself a reputation equalled by no other laboratory of its character in the country, because of the excellence of its work. Being supported by a regular fund, there are advantages connected with it which one will not find in other laboratories which are dependent upon subscriptions. Some excellent specialists spend their summers at this station, and the character of their work is shown in the bulletins published from the laboratory. Although Beaufort is not remarkably rich in variety of forms, still this is counterbalanced by the abundance of certain very interesting animals, for the study of which no better place than Beaufort can be found. As the Gulf Stream strikes on this coast, there are many interesting embryos found in the water. The building is a two storied house made to serve as a laboratory, and it is placed within a few feet of high-water mark. The location is a low sandy shore in a rather warm climate, but this is necessary on that coast where nothing else is found. For collecting purposes a steam-launch and sail-boat are used. It is under the direction of Prof. W. K. Brooks, who has done much towards making it what it now is.

Much further north, at Newport, Rhode Island, is another laboratory of a somewhat different character. It is under the charge of Prof. Alexander Agassiz, who, with a few assistants and some advanced students from Harvard College, carries on his investigations on the sea-shore. Dr. F. Walter Fewkes and C. O. Whitman study regularly at this laboratory. Because of its private character it should rather be classed with the former private laboratories which investigators were accustomed to establish at some favourite place on the sea-shore than with the general laboratories for students, though a certain limited number are admitted each summer. The advantages for study are limited, and the locality rather poor.

In the southern part of Massachusetts, at a place called Wood's Holl, the chief marine station of the United States is stationed. This is the Laboratory of the United States Fish Commission. Since 1871 the Fish Commission has each year been located at some point on the New England coast, investigating principally the specific characters of the marine fauna. Prof. Baird, the Commissioner, has had the direction of the Commission since it was first originated, and with the assistance of such eminent American naturalists as Goode, Bean, Verrill, Smith, and Sanderson Smith, the previously unkown New England fauna has been thoroughly studied, and certain parts of the North Atlantic deep sea carefully studied. For many years all the work has been done by specialists employed by Government, in a poorly adapted laboratory; but now a new building is being erected for the express purpose of serving as a laboratory, and it will be fitted up with all the modern conveniences for zoological and microscopical study. Being supported by an ample Government fund, it is expected that there will be a good library connected with it, and we know that there will be a supply of large aquaria, and that all necessary chemicals will be supplied. In addition to the tables for regular *employées*, there will be room for a limited number of students from some of the larger colleges, who will thus be offered the finest advantages for zoological study to be found in America. For the use of the laboratory there is a steam-launch, and many small boats, while the two steamers *Albatross* and *Fish Hawk* are constantly bringing in material from the deep sea and surface of the ocean. Wood's Holl is excellently adapted for the purposes of a summer laboratory, both because of climate and variety and abundance of animal forms. The work already done from the old laboratory is of world-wide renown.

This ends the list of those laboratories intended solely for advanced students. Of the other class, the Summer Institute at Cottage City, Mass., is an example. This is a summer educational institution covering a wide variety of subjects, and intended for teachers who are willing to

spend their summers in quiet study. Courses of lectures are given in various subjects, one of which is natural history, and the students can, if they choose, supplement their course by laboratory study. It is exceedingly elementary, and none but beginners attend.

Of a similar character, but of more importance, was the Summer School of Natural History at Salem, Mass., under the direction of Prof. E. S. Morse. The principle upon which this school started was wrong. The originators seemed to have the idea that courses of lectures were essential to the success of the school. Such lectures, if delivered by men of reputation, were costly, and to meet the expenses of the school a large attendance was necessary. But in America the sciences are not studied by a sufficient number of people to supply such a school, dealing in a limited branch of science, with enough students to defray the cost of lectures; and few students can afford to pay large tuition fees. So it was that the Salem School had to depend entirely upon outside aid for its continuance, and this being withdrawn, the school was obliged to break up a few years ago. It is, indeed, unfortunate that it was obliged to do this, because it was filling an important place in American scientific education by originating an interest in teachers of the public schools for this branch of study, and thus raising the standard of scientific teaching in the lower schools. If a regular fund could be placed at the disposal of some body of scientific men for the purpose of giving instruction to teachers in this way, it would be an important thing; but unless such regular support be established, other less expensive means of instruction in natural history for beginners must be looked to.

At Annisquam there is another laboratory, under the direction of Prof. Alpheus Hyatt, which has an entirely different plan for teaching beginners. At this laboratory both beginners and advanced students are allowed to study upon paying a merely nominal sum. No special instruction is given, but there is an instructor, Prof. J. B. Van Vleck, who helps the beginner over hard places in his studies. The student is given some animal to make a study of, and he is advised to examine it critically, dissect it, and make drawings of the parts, all without the aid of a book; and then, having found out all he can without aid, he is given some book to verify his observations. In this way the student goes through all the important groups of marine invertebrate animals, often learning for the first time that he can really see things for himself without the aid of books. The powers of observation are brought into play, and the first foundation of a successful student of Nature are thus laid. How much practical benefit this method of instruction will have in making original investigators cannot be told at present, because the school has been in operation for such a short time. The amount of knowledge possessed by the students at the end of the summer, compared with that with which they started, is certainly encouraging. That this is the proper method of teaching natural history has been satisfactorily demonstrated to those in charge by the results. Both sexes are admitted, and preference is given to those who are going to make use of the facts which they learn, either in teaching or in special investigation. The building is a plain one-story-and-a-half house, situated at the water's edge. It is well lighted and firm, and aquaria on each table are furnished with water from a tank filled by a windmill. For collecting purposes there are common boats, and Prof. Hyatt has a schooner yacht, in which he frequently takes parties from the laboratory upon dredging expeditions. Fifteen was the average number of students last summer, and they came from all parts of the country, being mostly teachers in small colleges and schools, and a few medical students and special investigators. In its inception it was intended for beginners, but advanced students are welcomed and given the best tables. The one unfortunate thing about this laboratory is that it is not established on a firm money basis, depending each year upon a grant of money from the Woman's Educational Society of Boston, which each year, so far, has generously given the funds for its maintenance. Neither the director nor the instructor receive salaries for their work, but furnish their summers free to the cause. For the purpose of making collections there is no better place on the eastern coast of the United States, with the exception, perhaps, of Eastport, Maine. The variety of animals is immense, and their abundance is also great, every condition necessary to an extensive fauna being present.

The last laboratory which we shall notice is the one which has long since passed out of active existence, in fact which died with its founder, the elder Agassiz. It was an immense building of wood on the island of Penikese, in Massachusetts, the outermost of the chain known as the Elizabeth Islands. The location was poorly chosen, for the fauna in the vicinity is poor, and there was no regular communication with the mainland, which was twenty miles distant. At one time during its brief existence it had a very large attendance, beginners particularly being attracted by the name of the eminent director. Lectures were given and laboratory practice was allowed each student. At this school such men as Fewkes, Faxon, Brooks, Whitman, and Alexander Agassiz, who have since become eminent in American science, received some of their first instruction in natural history. The death of Agassiz ended the institution, which if it could have been kept up under his direction would no doubt have equalled if not excelled any similar institution in the world. It is doubtful if even under Agassiz's direction this stupendous school could have been carried on, for we understand that the money basis was very insecure, and certainly the expenses were very heavy, and the tuition charges light.

RALPH S. TARR

ON A NEW METHOD FOR THE TEACHING OF SCIENCE IN PUBLIC ELEMENTARY SCHOOLS [1]

THE desirability of imparting to children some knowledge of the principles of science is now so generally agreed upon that this paper will be devoted not to the argument that science-teaching is necessary, but to a description of a method by which it may be successfully and thoroughly carried out.

In the "Code" under which the system of Government education is carried on in this country, science is mentioned under two heads:—

(1) As a "class-subject" (optional) which may be taught to any or all of the seven "Standards" under which the children are classed, and

(2) As a "specific subject" (also optional) which may only be taken by the children in Standards V., VI., and VII. The specific subjects named are—

1. Algebra.
2. Euclid and Mensuration.
3. Mechanics.
4. Latin.
5. French.
6. Animal Physiology.
7. Botany.
8. Principles of Agriculture.
9. Chemistry.
10. Sound, Light, and Heat.
11. Magnetism and Electricity.
12. Domestic Economy (*Girls*).

Either one or two (but not more than two) of these specific subjects may be taken by a child. The course in each subject is divided into three parts, so that a child must remain at school for three years in order to complete the study of any one subject.

The grants paid are at the rate of 1*s.* for a "fair" or 2*s.* for a "good" pass in class-subjects, and 4*s.* per pass in the specific subjects.

[1] By W. Jerome Harrison, F.G.S., Science Demonstrator for the Birmingham School Board. The greater portion of this article was read as a communication to the International Conference on Education, held at the Health Exhibition in July last, and is here reprinted by permission of the Executive Council.

To be successful in a public elementary school any scheme of instruction must be based upon the conditions of the Code. To these conditions, as they now stand, the following exceptions may be taken:—

(*a*) The teacher is forced to choose between geography and science as a class-subject. He may take *either*, but he cannot take *both*. As a rule he takes geography. It is to be hoped that in the future this restriction may be removed, and that a simple course of object-lessons on plants, animals, manufactures, &c., which would fulfil the requirements of science as a class-subject, will be given *in addition* to those lessons on geography which are really indispensable.

(*b*) The three years' course in a specific subject is too long, now that the child does not begin the study until it enters the Fifth Standard. Taking the case of the boys and girls presented for examination during 1883 in the Birmingham Board schools, we find in Standard V. 1864 children; in Standard VI. 482; in Standard VII. 85.

Tracing back the eighty-five Seventh Standard children, we find that they are the residue of 427 Sixth Standard children of 1882, and of 1223 who passed the Fifth Standard in 1881. It would probably be better to reduce each specific subject to a two years' course, and to allow Seventh Standard children to be examined in the work of the *two* previous years.

CHOICE OF SUBJECTS.—In considering what science

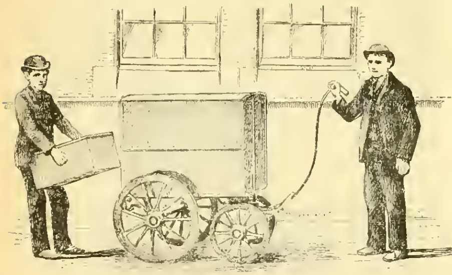

FIG. 1.—Hand-cart used for conveying apparatus from school to school.

subjects to select from those named in the Code, much will depend upon local conditions. Generally speaking, for boys' schools mechanics should be chosen, and for girls' domestic economy. As a second subject in town schools, either chemistry or magnetism and electricity may be recommended for boys, and animal physiology for girls. In country schools, principles of agriculture for boys, and botany for girls, will be found very suitable.

In the new Seventh Standard School, lately opened by the Birmingham School Board, there is an excellent workshop, fitted up with carpenters' benches, forge, lathe, &c., for forty boys. For this school I have drawn up a syllabus of a (proposed) new specific subject, entitled "Principles of Tools and Properties of Materials."

OBJECTIONS TO SCIENCE-TEACHING.—In time past three principal objections have been urged to the introduction of science-teaching into public elementary schools. These objections are:—

(1) *Want of Qualified Teachers.*—The ordinary teachers and pupil-teachers of our schools have not, as a rule, the sound knowledge of principles and practised powers of manipulation which are necessary in order to teach science with power and effect.

(2) *Want of Time.*—To *prepare* for a science-lesson, and to properly *clean and put away* the apparatus, requires more time than our closely-worked school-teachers are able to give. Some have also urged that "time" cannot be spared from the study of the "three R's," in which they consider incessant mechanical practice to be necessary.

(3) *Cost of Apparatus.*—To teach science practically—and it should be so taught to be of any value—a considerable sum must be spent in the purchase of apparatus. Thus the apparatus required for the three stages of mechanics costs about 75*l.*, and for domestic economy 65*l.*, and this is a considerable expenditure for a single school.

THE ITINERANT METHOD OF SCIENCE-TEACHING.—A method by which the principal objections urged against science-teaching in elementary schools may be overcome was suggested a few years ago by Col. Donnelly and Prof. Huxley, and it is not the least of the many services which these gentlemen have rendered to science and to education. This method has been carried out on a large scale, and with the most gratifying success by the School Boards of Birmingham and Liverpool, and the object of the present paper is to describe the manner in which the work is done in the former town.

The principal features of the itinerant method of science-teaching are as follows:—

(1) A science demonstrator is appointed, who should combine a practical knowledge of school-work and power to teach large classes with a thorough acquaintance with the branches of science which he is to teach.

(2) A "centre" is chosen in connection with some particular school, where a class-room may be set apart, or (better) a subsidiary building erected, where apparatus can be kept and the experiments prepared.

(3) A hand-cart must be provided (Fig. 1), into which the boxes containing the apparatus fit, and can so be conveyed from the science-centre to school after school by a strong youth. In this way one set of apparatus will serve for many schools. In each school department there must be a trestle-table, which should be placed in front of the class as the time for the science-lesson draws near. The hand-cart is brought to the school, the youth carries in the boxes, unpacks the apparatus, and places it upon the table. Then the science demonstrator walks in and gives the lesson. Afterwards the youth packs up the apparatus in the boxes, replaces them in the hand-cart, and marches off to the next school.

(4) A time-table is drawn up showing the exact time at which the science-lesson is given at each school, and its duration (forty-five minutes will be found suitable). A syllabus of each year's course of lessons must also be prepared (which should be distributed to the class-teachers and children), so that the subject may be gone through in a systematic way. As a rule it will be found possible for each science demonstrator to give four lessons per day, or twenty per week.

Each class should receive a lesson from the demonstrator at least once a fortnight. At each science-lesson the ordinary teacher of the class is present, and takes full notes of the matter given. During the intervening week the class-teacher *recapitulates* the science-lesson, giving such additional or new illustrations as he or she may be able to provide. The children then either write a general account of the lesson or answer three or four questions upon it, and the papers worked are submitted to the science demonstrator when he next visits the class.

It is plain that the itinerant system fairly meets the objections which have been urged against the introduction of science-teaching on the grounds of want of qualified teachers, want of time, and cost of apparatus. It also secures systematic and continuous teaching throughout the school year. The teaching is practical, and every fact or law is demonstrated experimentally. Wherever eight or ten schools are within a reasonable distance of each other, this plan may be carried into effect. Voluntary schools may combine with Board schools (as is done in Liverpool) to secure the services of a science demonstra-

tor, or small towns near to one another (as in Lancashire and Yorkshire, or in the Black Country), may unite for the same end.

APPLICATION OF THE ITINERANT SYSTEM OF SCIENCE-TEACHING IN BIRMINGHAM.—It was in June 1880 that I received my present appointment from the Birmingham School Board. Since that time the work in which I have been engaged has received the unanimous approval of the Board, but I ought especially to acknowledge the encouragement received from the Chairman—Mr. George Dixon—and from Dr. Crosskey, and the valuable advice given by the able and experienced Clerk to the Board, Mr. G. B. Davis.

Three assistants have been appointed, with a junior laboratory assistant, and two youths who work the two hand-carts which we now employ. The regular science staff thus includes seven individuals, whose salaries amount to 750*l.* per annum. In connection with the new Icknield Street School an admirable laboratory has been erected, at a cost (with fittings) of 1450*l.*, including a lecture theatre to seat eighty, a chemical laboratory and store-room, and a demonstrator's room (Fig. 2). About 400*l.* has been expended in the purchase of apparatus.

There are now thirty schools under the Birmingham School Board, attended by nearly 40,000 children.

In each of the thirty boys' departments Mechanics is taken as a specific subject by every boy in the Fifth and higher Standards; six departments take magnetism and electricity as a second specific subject.

In each of the thirty girls' departments Domestic Economy is taken as a specific subject by every girl in the Fifth and higher Standards; three departments take animal physiology as a second specific subject.

At the request of the teachers a few Fourth Standard children of exceptional ability are allowed to attend the science-lessons, since it is found not merely to do them good mentally but to induce them to remain longer at school.

The total number of children now receiving instruction in science in the Birmingham Board schools is, in round numbers:—

Mechanics	2400 boys
Magnetism and Electricity ...	300 ,,
Domestic Economy	1800 girls
Animal Physiology	100 ,,

In the framing of the syllabuses a wide interpretation has been given to these subjects; thus under the head of domestic economy as much elementary chemistry and physiology are taught as will enable an intelligent girl to comprehend the familiar facts of home life.

As a rule two science-teachers and two youths go with each hand-cart, so that the lessons to boys and girls go on simultaneously in each school. By this plan each hand-cart can visit four schools (eight departments) daily, while with a single teacher only two schools (four departments) could be visited.

The same lesson is given to class after class throughout the week. It is previously very carefully prepared by the science-demonstrator, is written out in full by him, and the experiments are tried over and the apparatus packed on Saturday morning, so that everything is ready for the start on Monday morning.

In each science subject there is but *one stage* taught in each school. Children entering on the subject join in at the second or third stage, as the case may be, so that all the children in any one department form one class, working at the same stage of the same subject. This plan simplifies the work wonderfully, and it is found in practice that the science subjects taken may be as conveniently commenced at any one of the three stages into which each is divided in the Code as at any other. Each stage stands quite by itself, and each may be considered in turn as forming an introduction to the other two.

RESULTS OF THE SCIENCE-TEACHING IN BIRMINGHAM.—The visits of the science demonstrator have been welcomed both by the teachers and children of the Board schools. The teachers have earnestly co-operated in the work, and much of its success is due to their efforts. With the children, the science-lessons have proved extremely popular. There is invariably a good attendance on the day of the science-lesson. Among the boys the half-timers then muster strongly, often getting leave to come in for that lesson only, and sitting with bare arms and rolled-up aprons, just as they have run from their work. In the same way big girls, who cannot escape from tyrannical babies, beg leave to bring their charges into the class-room; and I know of many a case where "mother" has been persuaded to change her "washing-day" because it

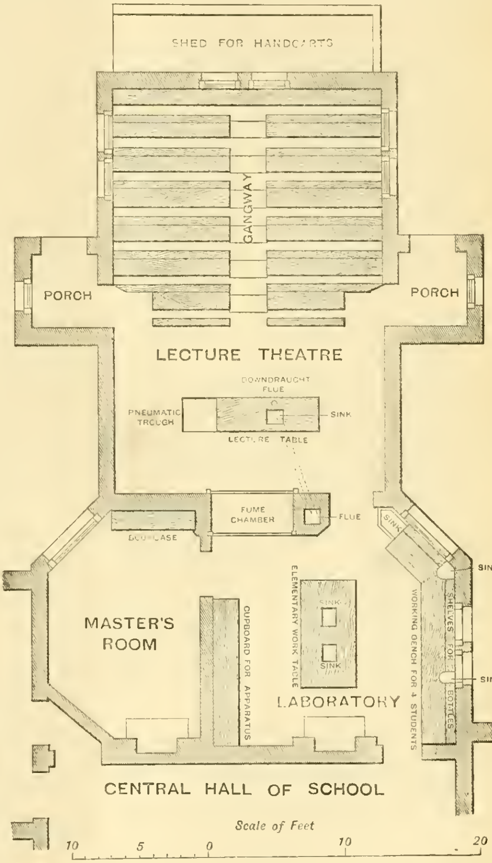

FIG. 2.

clashed with the day of the demonstrator's lesson in domestic economy. The teaching has evidently been carried home, for an irate landlord visited one school to "know what they meant by teaching children that his houses were not fit to live in!" the said houses being built "back to back," a practice the evils of which are pointed out in one of our domestic economy lessons. The large number of papers, essays, mechanical drawings, models of apparatus, &c., exhibited by the Birmingham School Board at the Health Exhibition will give some idea of the results of the work and of the eager manner in which it has been taken up by the children. So far from the science-lessons having interfered (by taking up time which would otherwise have been spent on the three R's) with the ordinary school work, the unanimous testimony of the teachers is that the increased intelligence of the children enables them to do their Standard work more easily. The idea has been very prevalent that by incessant mechanical practice excellence in the "three R's" can be secured; but the fact is that unless the intelligence be cultivated, no subject can be properly learnt. True education is culture of the mind, and mechanical acquirements have nothing in common with culture.

Applying to the matter the practical test of the Government examinations by Her Majesty's inspector, the results come out in a very satisfactory way.

Year	Number of passes in specific subjects	Percentage of passes in the three R's
1878	121	81·3
1879	424	82·0
1880 [1]	841	84·7
1881	1724	88·4
1882	3114	92·6
1883 [2]	3150	89·6

Another pleasing fact is the much larger number of children now found in the upper Standards. In 1879 (the year before the introduction of science-teaching) the percentage of children examined in Standards IV. to VII. was only 19·5; it is now 33·7.

The following extracts from the published reports of the Birmingham School Board prove that, in the estimation of those best able to judge, the teaching of science has proved a success.

1880.—"An important addition to the work of the Board schools has been the introduction of experimental lessons in elementary science. A science demonstrator has been appointed, and has now commenced work."

1881.—"In June 1881 the Board decided to appoint an assistant science demonstrator. The lessons in elementary science had proved so successful and attractive, that it was felt to be unfair that such advantages should be denied to some schools while they were afforded to others."

"These science-lessons are fully answering our expectations; the children are very attentive and much interested in the work; and, in addition to the useful knowledge they gain, their general intelligence is being developed."

1882.—"The success of the science-teaching has been strongly marked, both by the papers worked by the candidates for the science scholarships, and by the greater development of intelligence shown in regard to other subjects."

"As the teaching of science in Board schools has now become exceedingly popular, and many of the children have made considerable progress, six scholarships of 10*l.* each have been founded in connection with the Science and Art Department"

"Upwards of one thousand boys are now receiving admirable lessons in elementary science in the Board schools, and the result of this teaching is little less than marvellous."

1883.—"The teaching of elementary science in the Board schools has developed considerably during the year, the scholars taking great interest in it, and the results shown by the examinations being such as to prove that the knowledge imparted has been largely retained."

"Two great steps in advance have been made by the present Board. One is the establishment of science classes. The remarkable success which has attended these classes has been frequently alluded to, and is generally known."

Science Scholarships.—Twelve science scholarships of 10*l.* per annum have now been established in connection with the Science and Art Department. The boys who obtain these scholarships, together with an equal number selected as showing special aptitude for science, spend each Friday afternoon at the science laboratory in the study of analytical chemistry. All those hitherto examined have passed (and a large number in the first class) at the May examinations of the Department.

There are also two valuable science scholarships by which boys may pass from the Board schools to King Edward's Grammar School, and thence to the Mason Science College, their parents meanwhile receiving allowances of 15*l.* and 25*l.* per annum for their support. These scholarships are very keenly competed for, the usual number of boys examined being over 200. The examiner, Prof. Poynting, M.A., of Mason College, reports as follows:—

1882.—"Hardly any of the questions in my paper could have been answered without independent thought on the part of the candidates, and I had but very few answers showing a want of such thought. The boys showed that they had seen and understood the experiments which they described, that they had been taught to reason for themselves upon them, and that they were not merely using forms of words which they had learnt, without attaching physical ideas to them."

1883.—"The paper worked by the boy who stands highest on the list was an excellent one, and showed considerable power. The next five boys also deserve special mention as having done very good work. I think the general style of work sent in was very satisfactory. The average was not so high as last year, as the third stage of the subject was far more difficult, and the paper set was also much harder, but I think that quite as much ability was shown on the part of the candidates, and that the evidence of careful teaching was quite as strong."

Mr. Richard Tangye—the head of the great firm of Tangye and Co.—has taken a warm personal interest in the work, and his aid and countenance have been most valuable. He testifies strongly to the great improvement of his young "hands" since the introduction of the School Board system in Birmingham.

Summing up the matter, the results which we hope to obtain from this science-teaching, and which indeed have already manifested themselves, are:—

(1) The general quickening of the intellectual life of the school.

(2) The imparting of scientific knowledge and method to children which will be useful to them in after life, and which will cause many of them to continue their science-studies in evening classes.[1]

(3) The discovery of children of exceptional ability, and their support by means of scholarships.

(4) The instruction of the school-teachers in scientific principles, which they may apply to the general work of the school.

Evening Work in Science.—The work done among the teachers by means of evening science classes in connec-

[1] Science demonstrator appointed June 1880.

[2] Mundella Code introduced, by which Literature (in which 1435 passes were made in preceding year) was removed from list of specific subjects. The general requirements of this Code being higher, there was a slight drop in the percentage of passes for this year

[1] The last Report of the Birmingham and Midland Institute speaks of the influx of youths into the evening science classes—"the result doubtless of the science-teaching now carried on in the Board schools."

tion with the Science and Art Department has been of an important character. The Birmingham School Board employs about 800 teachers, and it now provides education, by means of training classes, for about 450 (the pupil-teachers and uncertificated assistants). The growth of the science work in this direction will appear from the following table:—

Year	Number of Certificates obtained	Number of First Class Certificates awarded	Gross Grant
1881	24	0	£18
1882	91	18	£108
1883	100	24	£124
1884	173	33	£197

It is very important to elementary school teachers to do well in science, since (by a regulation of the Education Department) those who have passed in science have a certain number of marks added to those which they obtain for other subjects at the Queen's Scholarship and Certificate Examinations, through which all these teachers have subsequently to pass.

Electricity and magnetism has been taught to the pupil-teachers, and physiography to the assistants.

When evening science lectures are given, however, no school-work can be done by the demonstrators in the afternoon of the same day, as the time is taken up with the preparation of the experiments, &c., for the evening lectures.

The Board possesses an excellent optical lantern presented by Messrs. R. and G. Tangye as a token of their appreciation of the science-teaching and with its assistance the science demonstrator gives popular evening science lectures in the various schools, taking subjects such as will be likely to awaken the interest and increase the intelligence of the children, as "Wild Animals in the Zoo," "The Star-lit Sky," "Two Days in London," "A Voyage to the Moon," &c. Occasionally, on fine evenings, the elder children are shown the moon, planets, double-stars, &c., through a three-inch achromatic telescope (refractor). These expositions tend to attract children to school, and to improve the regularity of the attendance.

COST OF THE SYSTEM.—The following rough balance-sheet for the year 1883-84 shows the very small cost at which the work of science-teaching is carried on in Birmingham:—

	£	s.	d.
Receipts.			
Half of Government Grant on specific subjects ...	160	0	0
Grant from Science and Art Department ...	150	0	0
	£310	0	0
Expenditure.			
Salaries ...	750	0	0
Interest on cost of buildings and apparatus ...	70	0	0
Renewal of apparatus and cost of materials ...	50	0	0
	£870	0	0

Net cost to the Board ... ... £560 per annum.

As a penny rate yields 6000*l.*, it will be seen that the cost of this system, by which more than 4000 children, distributed over sixty school departments, receive regular and practical science-lessons, amounts to only one-tenth of a penny in the pound, or to 9*l.* 10*s.* per annum for each school department. It must be remembered also that the full benefit of the system has not yet been reaped, and that the grants will certainly continue to increase. Credit has only been taken for one-half of the grant for the specific subjects.

TEXT-BOOKS.—Failing to meet with works exactly suitable for the wants of the children, the science-lessons in mechanics and in domestic economy have been written out in full, and are now published by Messrs. T. Nelson and Sons. Similar works on magnetism and electricity and on chemistry are nearly ready for issue. Each work consists of three small volumes corresponding with the three years' course prescribed by the Code. These books have already been adopted by the School Board for London, the Irish Intermediate Education Board, and other important educational bodies.

SCHOOL MUSEUMS.—For use in object-lessons, and as a constant source of pleasure and instruction, a small collection of typical objects stored in a glass-fronted cupboard ought to be placed in every school. Such cupboards are now being supplied to the Birmingham Board schools, and it has naturally fallen to the lot of the science demonstrator and his staff to assist in the mounting, naming, and classification of the objects with which the cupboards are, at little or no expense to the Board, to be filled.

CONCLUSION.—Since the commencement of this system of practical instruction in science in Birmingham, many eminent men have visited the schools to see it in operation, and they have been unanimous in their approval. In the "Instructions to Inspectors" issued by the Education Department, the system receives official sanction and commendation:—"You will often find that these (specific) subjects are most thoroughly taught when a special teacher is engaged by a group of schools to give instruction in such subjects once or twice a week, his teaching being supplemented in the intervals by the teachers of the school."

The Commissioners for Technical Education visited the Icknield Street Centre a few months ago, heard science-lessons given, and examined fully into the work. In their valuable Report, recently issued, they say:—"We could hardly overstate our appreciation of the value of the plan of giving instruction in natural science by special teachers as carried out in the Board schools of Liverpool and Birmingham, where the employment of a well-qualified science demonstrator insures the sound character of the instruction, whilst the repetition of the lesson by the schoolmaster enables him to improve himself in the methods of science-teaching."

Within the present year the work has been crowned by the opening of a Technical School for Seventh Standard boys, situated in the centre of the town, and fitted with an admirable laboratory (for forty boys), lecture-theatre, workshop (for forty, with three lathes), room for drawing, class-rooms for the ordinary subjects, and a capital dining-hall, &c. The building has been adapted, fitted (at a cost exceeding 2000*l.*), and presented rent-free to the Board by Mr. George Dixon. This school will constitute the last link of the chain of elementary education supported by the town, and who can doubt that in it will be laid the foundation of many a good work, both for the individual and the community.

NOTES

MR. J. J. THOMSON has been elected to fill the post of Cavendish Professor of Experimental Physics in the University of Cambridge in succession to Lord Rayleigh. A numerously signed requisition to Sir Wm. Thomson to become a candidate was declined.

CAMBRIDGE was *en fête* on Monday. Peterhouse, the oldest collegiate institution in the University, was celebrating the six-hundredth anniversary of its foundation. It was stated at the dinner that one-third of the present Fellows were Fellows of the Royal Society.

IT is announced that the International Sanitary Conference, which Signor Mancini proposed some time ago, will meet at Rome in February or March. Later on another Conference, also suggested by Signor Mancini, will meet to consider the possibility of some agreement for the mutual execution by the Signatory Powers of legal judgments.

The monthly weather review of the Signal Service, prepared, as announced for the first time in the August number of *Science*, by Second Lieut. W. A. Glassford, has come to be a quarto of twenty-eight pages, with five charts. This is a good growth from the four small pages and three charts of the first issue, eleven years ago. Then, the headings were storms, anti-cyclonic areas, temperature, precipitation, peculiar phenomena and facts, rivers, and cautionary signals: now, all these subjects are treated in much greater detail; and among the many additional topics there may be mentioned atmospheric pressure and its range (illustrated by a new style of chart), Atlantic storms and ice, range of temperature, frosts (illustrated by a chart for August 9 and 25), winds, local storms, tornadoes and thunderstorms, sunsets, drought, two and a half pages on the earthquake of August 10, meteors, and notes of State weather services for Alabama, Nebraska, Tennessee, Missouri, Louisiana, Ohio, and Georgia. The storm-tracks for the month are remarkably regular, and, with insignificant exceptions, all lie north of the Great Lakes and St. Lawrence: no tropical cyclones were felt along the sea-coast. Nine tornadoes are reported, and many violent thunderstorms. Some of the results of the special studies of the latter, undertaken by Mr. H. A. Hazen during the past season, take form in a brief summary, from which it appears that the mean distance and direction of the 900 thunderstorms reported in August, from the centre of the broad cyclonic storms in which they occurred, was 515 miles, a little west of south. A full account of these studies will be of much value and interest. Most of the observations on meteors are of small value, and, at best, they have but an etymological connection with a weather-review.

The completion of the Lick Observatory is stated by *Science* now to depend upon the successful making of the disk of glass for the objective of the large telescope. The main dome cannot be made till the focal length of the large equatorial has been determined.

A member of the Institute of France has brought forward a scheme for the foundation of a number of annuities, of the value of 80*l*., 160*l*., and 240*l*., to aid scientific men in the prosecution of experimental work, offering to subscribe 200*l*. towards the realisation of the scheme out of his own pocket. If the Government, who will soon have to decide on the application of Giffard's legacy of over 200,000*l*., thought fit to patronise this scheme, they have the means of giving it practical embodiment on an extensive scale.

In commemoration of the services to astronomy rendered by the French observers of the transit of Venus in 1874, the French Government have placed in the National Library of Paris a large monumental vase, designed and manufactured at Sèvres, bearing the following inscription: "La République Française à MM. Janssen, Bouquet de la Grye, André, Fleuriel, Hérault, Mouchez: Passage de Venus sur le Soleil en MDCCCLXXIV. Hommage du Gouvernement Français au Science." This vase, about 2 m. high by 1 m. broad, at present standing at the entrance of the Reading Room of the Library, will remain there for public inspection for some time, after which it will be removed to the Gallerie Mazarine, which contains a collection of rare manuscripts and other treasures.

A number of scientific men in Paris having founded a club called "La Science," for the purpose of dining together at stated times, recently entertained M. Chevreul at a banquet. The toast of the occasion was proposed by M. Jamin, the new Perpetual Secretary of the Academy of Sciences. M. Pasteur has been nominated Chairman of the next banquet. A similar club was instituted six years ago under the name of "Banquet de la Presse scientifique."

In his discourse on re-election to the Presidency of the Biological Society of Paris, M. Paul Bert stated that he had intended endeavouring to summarise the work of the Society during the preceding five years that he had held the office. But he found the task so difficult on account of the mass of facts presented by the publications of the Society, and the brevity of the papers, that he decided to abandon the idea. He promised, however, in future, at the commencement of the annual sessions, to sum up rapidly the progress realised during the preceding one. The scientific world will doubtless look forward with interest to the annual statements of the advance of biological research thus promised.

The Museum of the International Association at Brussels has just received a large collection of birds of all kinds, sent from Karema by Lieut. Storms; and also a collection made by Mr. Stanley during his last visit to the Upper Congo, consisting of utensils, furniture, musical instruments, arms, &c.

The laying of the foundation-stone of the new Sorbonne buildings will take place in a few days, the houses which covered the site intended for the new edifice having been all pulled down and the ground around the old Sorbonne to the extent of several acres having been levelled. The new buildings are to be pushed on rapidly, and the plans connected with the undertaking contemplate giving quite a new aspect to this part of the Quartier Latin. The enlargement of the Sorbonne was projected by Napoleon III. some years before 1870, and he had so far made a beginning with the work as to pull down several houses, and with all due state lay the first stone towards the additional structures in contemplation. The "first of the first stones" so laid down has been removed, though there is a rumour current that after search this first stone has not been found, and people are at a loss to know what has become of it. At all events the laying of the second of the first stones of the new Sorbonne will shortly be celebrated with becoming ceremony.

The International Society of Electricians has decided to hold an exhibition in January next, on the occasion of the first general meeting. The exhibition, which will last several days, is to be held in the rooms of the Observatory of Paris, which have been lent for the purpose by the director.

According to the *Oxford Magazine* there have been several interesting additions lately to the collection of casts in the University Museum. By the side of the skull of a Dinotherium now stands the skull of a Mastodon. Casts of the complete skeleton of Halitherium, the curious Miocene Sirenian which possesses distinct though small hind limbs, and of the hind and fore feet of the gigantic *Iguanodon Bernissartensis*, the original of which is one of the chief features of the Natural History Museum at Brussels, have also been added.

An exhibition of the arts, industries, and natural productions of the Malay Archipelago was opened under the patronage of the Government of the Dutch East Indies at Batavia last month. The productions of Penang, Singapore, North Borneo, and Sarawak are largely represented.

Prof. Mell, director of the Alabama Weather Service, announces that through the liberality of the chief signal officer and of several railways; daily weather signals predicting changes of weather and temperature, will in future be displayed at upwards of 100 telegraph stations in the State of Alabama. The predictions will be received by the director at an early hour every morning from the Signal Office at Washington, and then promptly distributed along the railways. On paying about six dollars, the cost of the signal flags, any town or telegraph station will receive free telegraphic warning of the daily weather changes. Only about five minutes are required to set the flags. A similar

extension of weather signals has been for some time in operation in Ohio and in a portion of Pennsylvania.

THE last Consular Report from China, published as a Parliamentary Blue-Book (China 6A Trade Reports), contains the appendixes to the annual report of the English Consul at Ichang. They deal with the animal, fossil, mineral, and vegetable products of the Ichang district. A considerable part of the *flora* appears to be employed only for medicinal purposes. The extracts from Mr. Gardner's diary of his travels through the province are sometimes extremely interesting; his account of a visit to the fossil quarries is especially so. Three kinds of fossils found in the district are staples of trade, the pagoda stones *Orthoceras*), kosmos stones (*Ammonites*), and the "stone swallows." The first is found in the slate, and is cut, and either framed as a picture, or made into ornamental furniture. The *Ammonites* receive the name of "kosmos stones" from their resemblance when polished to the Chinese symbol for kosmos. The so-called stone swallows are ground down, and, like much else in that region, used as medicine. These are fossil bivalves, and the name is given to them because the natives believe that they fly about underground in the same way that the swallow flies in the air. The fossil cutters appear to be a separate guild, and mostly converts to Christianity. The tools are merely a saw and a chisel. They prod about the slate until they find an *Orthoceras*, which they think will be perfect; they then cut out a slab, which they saw into two or three thin planks, so that the fossil looks like a white picture of a pagoda on a black ground. These various fossils are close together in a region at least thirty miles long, and Mr. Gardner thinks that there is hardly a cubic foot of the limey slate which does not contain a fossil or the fragment of one.

THE most recent link in the long chain of telegraph lines which is spreading with such rapidity over China is the land line from Shanghai to Canton. A line from Pekin to Tientsin was opened a few months ago, and the capital of China was connected directly with London. Now the capital of Southern China is joined with the metropolis in the north; and as Canton was put in communication by telegraph with the frontier of Tonquin at the outbreak of the present political troubles in the latter district, the telegraph now stretches in an unbroken line from Pekin in the north to the most southern boundary of the Chinese Empire, and a message either from London or Pekin might reach the head-quarters of the Chinese forces on the Tonquin frontier in a few hours. Four years ago the only telegraph line in China was one about six miles in length, stretching from Shanghai to the sea, and erected to inform the mercantile community of the arrival of vessels off the mouth of the river. The next important line constructed by the Chinese Government will probably be one uniting Pekin with the great northern lines across Siberia at Kiachta. This will have to cross the whole of Mongolia, and will give the capital of China a third alternative telegraph route to Europe, a matter to which some political importance is believed to be attached in China. As already pointed out in NATURE, this extraordinary development is due solely to political considerations.

A COMMISSION appointed by the French Government to consider the best method of developing the mineral wealth of Annam and Tonquin has just issued its report. It lays down a programme for a mining mission, which it has been decided to send out there, and suggests the appointment of two separate missions. The duty of the first of these would be to ascertain whether the metalliferous deposits stated by Annamite documents to exist in two north-western provinces of Tonquin do actually exist there, and how far it would be possible to work them profitably. The second should investigate the copper deposits of the delta, and subsequently extend its labours into Annam. A draft mining law for these regions has also been proposed. Its special provisions are those relating to the mutual rights of the owners of the soil and those who have been granted concessions to work the mines; to administrative intervention (which it is recommended should be as rare as possible) with private mine owners. The broad policy laid down by the Commission is very liberal, not only to the natives, whose rights or alleged rights are to be scrupulously respected, but also to other nations, whose subjects are, for mining purposes, to be placed on the same footing as Frenchmen. Work, it is said, can take place at once on the coal-measures known to exist on the coast of Tonquin, as well as in the adjacent islands.

THE several correspondents of *La Lumière Electrique*, who have been sent to report on the progress of electricity in America, have returned to Paris, and are preparing their reports, which will be published next year.

THE site for the Centennial French Exhibition has been selected. It is to be held on the Champ de Mars, which belongs to the War Office, but will be given up to the city of Paris. A part of the Champ de Mars will be sold for building purposes. The Central Palace of the Exhibition will be made permanent and used for yearly exhibitions like those held in London at South Kensington.

PROF. T. C. MENDENHALL, *Science* states, has been appointed Chief Electrician of the U.S. Signal Bureau.

THE additions to the Zoological Society's Gardens during the past week include a Silvery Gibbon (*Hylobates leuciscus* ♀) from Java, presented by Mr. C. H. A. Hervey; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mrs. J. N. L. Boljahn; a Common Roe (*Capreolus capræa*), British, presented by Mr. C. Hambro; a Common Rhea (*Rhea americana* ♂) from South America, presented by Lady Brassey, F.Z.S.; a Tawny Owl (*Syrnium aluco*), European, presented by Mr. W. P. Clark; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mr. R. O. S. Ogilby; a Greater Black-backed Gull (*Larus marinus*), British, presented by Mr. T. E. Gunn; a Herring Gull (*Larus argentatus*), a Common Gull (*Larus canus*), three Greater Black-backed Gulls (*Larus marinus*), three Black-headed Gulls (*Larus ridibundus*), British, presented by Mr. W. H. Fielden, C.M.Z.S.; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, a Brush-tailed Kangaroo (*Petrogale penicillata* ♀) from New South Wales, a Hairy-fronted Muntjac (*Cervulus crinifrons* ♂), two Michie's Tufted Deer (*Elaphodus michianus* ♂ ♀) from China, a Tawny Owl (*Syrnium aluco*), European, a Hobby (*Falco subbuteo*), British, deposited; two Common Guillemots (*Lomvia troile*), a Razorbill (*Alca torda*), British, purchased.

OUR ASTRONOMICAL COLUMN

OCCULTATIONS OF ALDEBARAN.—The next series of occultations of Aldebaran visible at Greenwich commences on February 22, 1885, and terminates on October 6, 1887. The dates and mean times of immersion and emersion are as follow:—

			Immersion h. m.	Emersion h. m.
1885	February	22	5 17	5 50
	March	21	11 43	below the horizon
	November	22	9 48	10 57
1886	January	16	7 48	8 49
	April	8	5 8	5 54
	November	12	18 27	19 16
1887	January	6	12 17	13 15
	March	2	5 47	6 4
	October	6	15 20	16 2

There are therefore eight occultations in this series in which both immersion and emersion are visible, and one in which only the immersion occurs while the star is above the horizon at Greenwich. In the last series, which commenced September 28, 1866, and ended on August 2, 1869, ten occultations were wholly visible.

Occultations of Aldebaran are on record as far back as the year A.D. 491; it is stated in the Chinese Annals that the star was occulted at Nankin on March 29. Apparently the first occultation observed in Europe was found by Bullialdus in a Greek manuscript, which thus describes it:—"Anno 225 Diocletiani, Phamenoth 15 in 16, vidi Lunam sequentem claram Hyadum post accensas lucernas, digiti unius ad summam semisse. Videbatur autem occultasse ipsam. Stella quippe apposita erat parti, per quam bisecatur limbus Lunæ illuminatus." Bullialdus makes the date A.D. 509, March 11, and an approximate calculation shows that he is correct. New moon fell about 7h G.M.T. on March 6.

ENCKE'S COMET.—This comet at its present return will be observable in these latitudes in the early evening hours before perihelion. The following ephemeris is for 6h. G.M.T.:—

1885	R.A. h.	m.	s.	Decl. °	′	Log. distance from Earth	Sun
Jan. 1	22	55	26	+3	57·8	0·1526	0·1309

27	23	25	37	6	1·0		
28	23	27	4	6	7·2		
29	23	28	31	6	13·5	0·1033	9·9619
30	23	30	0	6	19·7		
31	23	31	29	+6	25·0		

The intensity of light expressed in the usual manner is 0·27 on January 1, and 0·51 on the last date of the ephemeris.

GEOGRAPHICAL NOTES

AN interesting project was laid before the Associated Swiss Societies of Geography at their meeting at Berne last month, by M. Mullhaupt. He suggested the formation of an international geographical bureau for the following purposes:—(1) To carry out the resolutions arrived at by the International Geographical Congresses. (2) To make exchanges every month, or oftener if need be, between the eighty odd geographical societies; in place of each society sending its own publications in eighty different directions, it would only have to send them all at once to the bureau, which would do so. This, he claims, would save both time and money. (3) To publish, in the four or five principal languages, a summary of the contents of the publications of the various geographical societies; instead of each society being forced to do this for itself, a single examination would suffice to put them all *au courant* with what has been done all over the globe. There would in this way be the further advantage of knowing what was published by societies like the Geographical Society of Japan, the publications of which are in a language not generally known in Europe. M. Müllhaupt thought that the idea was not a difficult one to be carried out; the expenses would be shared by the numerous societies interested. These contain approximately 38,000 active members, and doubtless the countries having an interest in the progress of the geographical sciences would take part in a central organisation of the nature here suggested.

THE last number (Band xi. No. 8) of the *Verhandlungen der Gesellschaft für Erdkunde zu Berlin* contains two papers on West Africa: one accompanied by an excellent map, by Herr Flegel, of his recent journey along the Niger to Adamawa; the other, by Herr Reichenow, on the Cameroons, and the German colony there. Dr. Lopez writes on the Argentine States, and the importance of the German element in the foreign population there.

THE investigation of the subterranean course of the Reka River has been actively pursued for some time past by the Coast Section of the German and Austrian Alpine Society. The Reka is that mysterious river which, coming from the Schneeberg in Carniola, loses itself in the caves of the Karst, and after a subterranean course of more than thirty kilometres, breaks out of the ground near San Giovanni di Duino, is then called the Timavo, and eventually flows into the Bay of Monfalcone. Already, on March 30 last, a part of this subterranean course was investigated by a party starting from the village of St. Canzian, where a celebrated cave is situated, into which the Reka falls with thundering noise when the water is high. In September a second exploration was made. The first subterranean cave is called the Rudolfs Dome; it was from here the explorers started in two boats. First, they passed a canal about sixty metres in length, very narrow, and bounded by rocky walls one hundred metres in height; then a large cave was reached, where the party landed and fastened the boats, as waterfalls and rapids prevented further progress in boats. The underground journey was now continued on the rocky banks, the river being crossed several times on ladders. Thus six waterfalls were passed, and a seventh was reached. Altogether the explorers penetrated to a distance of between two and three hundred metres underground.

BULLETIN No. 5 of the U.S. Geological Survey is, *Science* remarks, a dictionary of altitudes in the United States, compiled by Henry Gannett, chief geographer of the Survey. It is essentially an extension of the "Lists of Elevations," prepared by the same author for Hayden's Survey; but, with the present broader organisation of the Geological Survey, the lists now appropriately include the whole country, while the earlier editions were concerned chiefly with the region west of the Mississippi. A list of authorities fills eight pages, and railroad abbreviations occupy eight more; then the States and stations follow alphabetically, the number of altitudes given being about 18,000. It is stated that the collection of railroad profiles for Pennsylvania is exceptionally complete and admirably adjusted, making the portion of the dictionary referring to that State by far the fullest and most satisfactory. By an unfortunate oversight, it is not stated whether the base level is high, mean, or low tide.

AT the recent meeting of the Ethnological Section of the Imperial Russian Geographical Society a paper was read describing Adrianow's journey through the Altai Mountains in 1881. The traveller was only able to take four companions, on account of the meagre funds at his disposal; nevertheless he was able to obtain excellent results, and to penetrate hitherto unknown regions. Although the southern slopes of the Altai Range have already been the object of investigation of various students, such as Pallas, Ledebur, Humboldt, and others, the eastern part of the region, the vast districts between the River Tom and the Government of Yenisei, have been almost a *terra incognita*. Adrianow's expedition started from the town of Kustnetsk, crossed the River Lebed, examined Lake Teletsk, touched Chulshman, Jan, and Agalan, crossed the Shapshal Pass, advanced to the River Kemchik, and sought for and found the sources of the Yenisei. They travelled through the region through which the river flows to the town of Yeniseisk, where the expedition came to an end. Throughout the journey Russians were found only around the sources of the Yenisei and on the River Usg. The population of the Altais is composed of sectaries who emigrated thither during the last century; their existence was wholly unknown until 1868, when they were by chance discovered by a Russian officer who was surveying there. Adrianow met similar colonies at Tobut on Koko-nor. These were founded in 1800. The colonists are described as savage and predatory. Besides these the traveller visited the so-called Black Tartars, on the rivers Koudoma and Luida—a tribe which has only once before been visited and described. They are regarded as descendants of the great Finnish and Turanian tribes, but hardly anything in an anthropological sense is known about them. The travellers also brought back a considerable number of pictures of monuments and works in stone, which exist among the Sajans and in Mongolia. Those of monuments to the dead are very interesting; some of them are merely

conical heaps of stones, while others are laid quite flat and are surrounded by a circle of larger stones; a third kind exhibit a primitive art of stone-cutting, the stones bearing a distant resemblance to the human body. Frequently around the graves the bones of horses which had been brought as sacrificial offerings, were found, as were also certain Runic inscriptions.

M. ADRIANOW, in his journey through the Altais, notices the existence in these regions of immigrant communities which have been forgotten and which have been re-discovered by chance. It is also reported from St. Petersburg that a similar discovery has been made elsewhere in Siberia. In the course of a prolonged inspection of his province, the Governor of Irkutsk (Governor-General of Eastern Siberia?) came across a town called Ilim, with 500 inhabitants, 150 houses, and four ancient churches, with remarkable relics of Cossack times. It is still under the republican rule of a *vetche*, or public assembly, convoked by a bell, as in old Novgorod the Great, although the new municipal institutions were supposed to have been applied to that part of the Empire ten years ago. Not one of the inhabitants can read or write.

AN important geographical work on Austro-Hungary is now being produced in parts by Mr. Alfred Hölder, the publisher, of Vienna. The author, Prof. Umlauft, gives in alphabetical order the names of the various States and peoples of the Austro-Hungarian empire, as well as those of the more important districts, mountains, rivers, and towns, with their meanings. He does not, however, confine himself simply to present names, but also gives the forms employed formerly and the various changes which the name has undergone from the earliest times down to the present day. The work is thus historical and philological. The total number of names treated will be between six and seven thousand. The first part, which has appeared, contains 1041 names, from Aa to Donau. Geographical names, it is said, not only have their history, they are themselves pieces of history. The distinction between the German and Slav names of places is characteristic. The great majority of the German village names are connected with those of persons, probably the founders or original owners, more rarely with that of the patron saint. Thus Simmering comes from Simoning, Hütteldorf from Utendorf, Hadersdorf from Hadrichsdorf, Kalksburg from Chadalhohisperg (*i.e.* mountain of one Chadalhoh), Domsdorf from Dominiksdorf. The change wrought in course of time in some names has been very great, and renders their explanation difficult. The Slav names, on the other hand, are mostly taken from the position of the place or some peculiarity in the neighbourhood. They also manifest great stability of form, and it is only in their Germanising that they have materially altered. Thus the Czech Brloh becomes in German Bierloch, Ratibor Rothwurst, and Radoina Rothweim. The Czech Lhota, which means simply a settlement which is free from taxation, assumes in German such various forms as Oehlhütten, Elhotten, Ellgoth, Wellhotten, Welhütten, Wellhütten, Mehlhüttel, Malten, and others. Even real German names have undergone the same eccentric change, and names which in their original form are quite clear in their meaning have by a slight change become incomprehensible; thus Donnersmark is really Donnerstagmarkt, or Thursday Market. It may be remembered that some articles in the *Times* during the autumn, followed by a long correspondence, did much interesting and valuable work of this kind for English place-names, though of course in a less regular and systematic form.

MR. IM THURN'S Roraima expedition left Kalacoon on October 16 with three boats and crews of seventeen Pomeroon and two Mazarooni Indians, and on the following day they ascended the first falls of the Essequibo. Simultaneously with their departure from Kalacoon, an expedition for Roraima, under the charge of a commercial botanist named Siedel, left Bartica for Roraima *via* Mazaroon. The two parties will probably meet on the mountain.

M. AYMONIER, a Saigon official, has recently returned from a journey of exploration in Indo-China. He left Saigon at the end of September last year to explore Southern Laos, and made a collection of the ancient Cambodian inscriptions. Having explored the intervening country, he reached Bangkok at the end of June last, and here he remained for some time to complete his studies on the Siamese kingdom. The result of his travels will shortly be published in the "Excursions et Reconnaissances," and he will afterwards proceed on another journey of exploration in Annam.

ROOTS[1]

IN treating of the roots of plants this evening, I may request you to dismiss from your minds any expectations or apprehensions of marvellous descriptions of tropical or rare roots on the one hand, or of a list of the peculiarities of various kinds of roots or so-called roots on the other, though it is not improbable that some of the facts will be, in part at least, new to some of you, as they certainly are to many people. I do not propose even to put any new discoveries before you. It has seemed much more to the purpose to show, as well as time will permit, that a vast amount of interesting and important information can be derived from a proper and systematic study of the roots of a common plant—information, moreover, which is important alike to the scientific botanist and to the practical agriculturist, two people who find they have more and more in common each day they come to know one another better. As the diagrams must in part have told you already, I propose that we meet on ground familiar, to a certain extent, to every one; and the sequel will show, I hope, that we have in no way acted unwisely in taking each other into confidence on the subject of an ordinary root, such as is well known to all of us. So much is this the case, that our study may be confined for the most part to the root of the common broad bean and a few other plants of our gardens.

[The lecturer then shortly described the germination of the common bean, maize, and a few other plants, and illustrated by diagrams the mode in which the first or primary root of the bean seedling emerges below, as the young seedling shoot (or "plumule") prepares to force its way upwards to the light and air. Next followed a short consideration of what this root may be said to be.] Anticipating matters to a certain extent, it may be shortly described as an organ for fixing the rest of the plant to the substratum, or soil, from which it absorbs certain food-materials. By confining our attention to this typical and well-known form of root, we may avoid any complexities resulting from the consideration of the more extraordinary cases occurring among the lower plants, or among curious aërial epiphytes, parasitic or otherwise, and other abnormal forms—forms which would demand several lectures by themselves.

The roots we have to consider, then, are organs for anchoring the rest of the plant firmly into the soil, and for absorbing certain matter dissolved in water from that soil. Obviously, we may do well to see, first, how the root gets into the soil; and secondly, how it accomplishes its objects when there.

When the young root first peeps forth from between the coats of the seed, it is seen to have its tip directed downwards towards the centre of the earth. Now this is not an accident; for if the seed be turned over, so that the apex of the root is made to turn upwards, its tip soon bends over, and again becomes directed downwards. [Mr. Ward then proceeded to explain, as shortly as could be done without detailed experimental evidence, that this persistent turning earthwards of the young root is due to a peculiar property, almost of the nature of a sensitiveness or perception to the influence of gravitation, and is not due merely to the weight of the organ.]

Next, evidence has been obtained to show that the tip of the root has a slightly rocking or swinging movement, which is more or less of the nature of the movements so well known in the case of the stems of twining plants; the tip of the root, in fact, not only moves earthwards, but tends to describe a very steep spiral as it does so. These successive very slight noddings to all sides of the tip as it proceeds in a line directed towards the centre of the earth are extremely slight, it must be borne in mind, but they may aid the point of the root to wriggle its way between the particles of earth in a loose soil, or to run down any crevice or hole it meets with.

Thirdly, in addition to its determined tendency to descend, though in a very slightly spiral course, the tip of such a root as we are describing has been found to be peculiarly sensitive to the contact of solid bodies. This extremely curious phenomenon could only be fully described by references to experiments and matters which we have scant time for. It must suffice, therefore, to state that there is evidence to show that the *extreme tip* of the root, on coming in contact with a hard resistant body, is caused to turn aside *from* that body, and if it comes simultaneously into contact with two bodies, one of which is harder than the other, it is caused to bend away from the harder of the

[1] Abstract of a lecture delivered before the Manchester Horticultural Society, in the old Town Hall, Manchester, on November 6, by H. Marshall Ward, M.A., Fellow of Christ's College, Cambridge, and Assistant Lecturer in Botany at the Owens College.

two. This property is all the more curious because, at a portion of the root a very short distance behind the tip, contact with a solid body causes that part of the root to curve *over* the touching body, much in the way that my finger is now curved over this wooden pointer. As already stated, time will not admit of our examining these very remarkable matters more closely—they form subjects for lectures in themselves.

But we have not yet finished our survey of what these sensitive tips of the roots are capable of. Experiments show that they turn towards a wet surface or atmosphere—a fact of great importance, and one which no doubt lies at the base of the explanation of the choking up of drain-pipes, &c., by the roots of neighbouring trees. Further, the apex of the root of such a plant as the bean we are considering avoids the light—avoids it as energetically as the leaves and green parts turn towards it. The two facts thus tersely put, viz. that the tip of the root tends towards a damp spot and avoids an illuminated one, are of course also in agreement with the rest of the behaviour of our germinating bean, and hence the root descends into the damp, moist, granular soil.

It is now time to see what sort of structure this wonderful root-tip possesses, and to inquire whence comes the impulse which drives it forwards into the soil—for it will be seen that while the forces producing the various curvatures which have been referred to tend to guide the apex of the root downwards between the particles of soil, towards the darker, moister, deeper parts, they cannot be expected to drive it into the soil.

In the first place, the tip is a firm, conical, smooth body, covered with a slippery, loose root-cap, as seen in the diagrams. Now, it cannot be too carefully borne in mind that the true tip of the root, beneath the covering cap, is resistant and somewhat elastic; it consists of multitudes of minute tightly-packed cells, each densely filled with protoplasmic substance containing very little water, and of a consistency resembling in some degree that of a well-made, hard-set jelly. Perhaps, indeed, a better idea of it may be gained if the conical tip of the root is compared to a firm, resistant jelly, cut up by delicate partitions into multitudes of minute blocks, which, however, are not separated from one another at all. In any case, it is clear that such a cone, if steadily and slowly driven by a persistent force from behind, is admirably adapted for penetrating between the particles of soil, especially if we bear in mind the following facts: (1) the cone is protected by a slippery cap of loose cells, which prevents the abrasions of the particles of soil from injuring the cells beneath; (2) the driving force is steady and continuous, and directed vertically, *i.e.* along the axis of the cone; (3) the tip oscillates slightly from side to side, and is thus probably (though not to any very great extent) insinuated between the earthy particles, no doubt being aided to a certain extent by other properties to which allusion has been made. It is of course obvious that the last thing we should expect of such a cone is that it could take up quantities of water from the soil: its structure is clearly in no way adapted for such a purpose, if only from the fact that there would be nowhere for the water to effect an entrance.

And now comes the question, What is this steady, continuous driving force from behind? Well, it is due to the simultaneous elongation of the hundreds of thousands of little cells situated a short distance behind the more rigid cone we have just examined. No doubt it seems a hard fact to grasp—that the absorption of water, and the intercalation of minute particles of substance in the interior of the cells shown in this diagram should be capable of steadily driving the apex of the root into the soil; but it is a fact nevertheless. Perhaps you will apprehend the matter more clearly if I offer you a well-known illustration which, it is true, does not exactly cover all the facts, but which will, at any rate, aid you in overcoming some initial difficulties. You are well aware that a wedge of wood driven firmly into a crack in a rock and then moistened, swells, and that it may swell so powerfully as to fracture the rock; very well, the elongation of the cells behind, which steadily drives the firm cone of the root forwards, is to a great extent due to the absorption of water, which causes each cell to grow longer. I say to a great extent, because, while the water is, on the one hand, absorbed in a slightly different way and enlarges the volume of each cell to a much greater extent, there are, on the other hand, forces at work which cause new particles of substance to be added to those originally composing the cells, and so fix the cells, as it were, in their condition of greater elongation, strengthening them at the same time. But this is not all. Besides growing longer, and thus driving the apex steadily forwards, the cells behind increase in diameter, and so push aside the particles of the soil with a force which would astonish you if I entered into figures; this, however, can only be adverted to here, since we must now pass to the explanation of one or two other points.

It is clear that, great as is the driving force supplied by so many elongating cells—and, of course, it is upon the simultaneous action of countless thousands of cells that the driving power depends—it would soon cease to be of much use unless a holdfast were insured at some point behind. This brings me to the consideration of an extremely important matter, and one on which I hope to make you quite clear. At first, while the root is still very young (as in this diagram), the weight of the seed above, with that of any soil covering it, seems to suffice to afford the necessary points of application; and this will doubtless be supplemented immediately afterwards by the increase in diameter of the upper part of the root.

When the root has attained some little length, however, a striking change takes place in its behaviour to the surrounding soil. First, let me call your attention to the following points, as illustrated by these diagrams. When the young primary root has attained a length of about four to six or eight inches—depending on circumstances which we need not occupy time in examining—the older portion nearest the seed has ceased to grow in length, and its surface is becoming clothed with a dense covering of very delicate hairs, which will be referred to in future as the "root-hairs." Each root-hair is an extremely slender sac—a sort of long tubular bladder, in fact—which possesses in virtue of its peculiar organisation an extraordinary aptitude for taking up water, and for attaching itself to the particles of soil with which it comes in contact. These facts are well illustrated by reference to these diagrams, to which I wish your attention for a few minutes.

From the delicacy of these root-hairs, and from their springing at right angles from the surface of this part of the root, radiating in all directions between the particles of soil, to which they immediately proceed to glue themselves, it is obvious that they are saved from being torn away as the tip of the root is slowly driven forwards between the particles of soil; if they were to arise on the tip itself, or on the parts which are elongating behind it, they would infallibly be removed by the abrasion of the particles of soil. Instead of this, however, they become developed on the parts behind in successive multitudes as those parts cease to elongate.

At the same time, the thousands of points of attachment established by the root-hairs afford the holdfast which becomes more and more necessary as the apex of the root is driven further and further forwards, and as the weight of the aërial parts of the plant, with their increasing surfaces exposed to wind and weather, become larger.

Meanwhile, leaving aside for the moment the consideration of how these millions of root-hairs take up the water and food-matters from the soil, the young root has been making preparations for obtaining a still firmer and wider holdfast on the soil, which will, at the same time, enable them to absorb water and food-materials at millions of new points further and further removed from the centre at which the primary root commenced its operations. To understand this, I must call your attention to this diagram, showing how the branching of the root proper is brought about. In the interior of the growing root a number of cells begin to multiply at certain points, and to form the young beginnings of lateral roots or rootlets; further back you see these young lateral roots upheaving the tissues of their parent root as minute knobs. By this time, however, these portions of the mother root have ceased to grow in length, and thus the tender little tips of the lateral roots can protrude and be pushed into the soil around without danger of being dragged off or injured, as they would inevitably be if this part of their mother root were still actively elongating. Notice carefully the exquisite adaptation to the circumstances, though brought about in a slightly different manner; no time is lost in the preparation of the young root branches within the tissues of the parent root, but the tender tips, as in the case of the root-hairs, only proceed to grow radially into the surrounding soil when the growth of the mother root in a direction across their long axes has ceased.

Time will not allow of our examining these matters more in detail; but I cannot avoid calling your attention to the fact that these lateral roots are sensitive to gravitation in a manner different from the primary root—they grow, not straight down towards the centre of the earth, but across the vertical, it may be more or less inclined, in different cases. In other respects they

resemble the primary root generally, in their turn producing root-hairs and daughter roots, which radiate from them in all directions into new portions of the soil, as shown in this diagram.

I need not do more than point out to you that it would be difficult to conceive of a series of adaptations better calculated to insure that the various parts of the root-system come successively in contact with the whole mass of soil traversed; and when your eyes follow mine over this diagram, you will agree that matters have become so arranged, so to speak, between the roots and the soil, that every part of the latter is laid under contribution. Notice how this vertical cylinder of earth is first bored through by the primary root, and then traversed in all directions by the root-hairs, in a wave, as it were, passing from above downwards. Next come the lateral roots, burrowing in all directions from the main shaft, and each in turn demanding toll from the cylinder around it by means of its wave of root-hairs. Then follow tunnelings along the lengths of each of these rootlets, and on all sides at right angles to them, until every nook and cranny has been investigated by these enterprising rootlets and their prying root-hairs. Quite apart from all else, therefore, the root-system obtains a greater and greater holdfast on the soil by driving its tips in on all sides.

But I must now draw your attention to some matters which throw even more light on our subject. The root-hairs, as they develop successively from above downwards on the primary root, or on the lateral rootlets, come into the closest contact with the particles of soil—contact so close and firm, in fact, that they cannot be torn away without injury. There are experiments to prove that their cellulose walls become actually moulded and gummed on to the solid particles of quartz, slate, and other rocks of which ordinary soils are composed, and this diagram shows how we can lift up a relatively large cylinder of soil adhering to the root-hairs of a young seedling.

Now you are probably aware that the sort of soil in which a healthy plant flourishes contains air-bubbles as well as water in the interstices between the particles, and into which the root-hairs become insinuated. Bearing this in mind, you will have no difficulty in understanding from the diagram how the root-hairs absorb the aërated water necessary for their well-being. I need simply make the additional remark that each little bag-like root-hair takes up the liquid water through its permeable walls into its interior, in some respects very much as a bladder full of a solution of sugar or salt would absorb water if placed in it.

But this water taken up by the root-hairs and passed on into the rootlets and so on up the stem (a process for which provisions are made which we cannot go into here), is not pure water; it contains, besides air, certain small proportions of the soluble matters found in all soils. It is, in fact, much like ordinary drinking-water from a well or spring, which always contains some matters in solution. But the roots want certain other minerals, which will not dissolve in pure water to a sufficient extent under ordinary circumstances. Well, the root-hairs, in making use of the oxygen which they, like all other living bodies, require, give off small quantities of acids which aid the solution of these more refractory matters.

And now I have finished—not because the subject is exhausted, but because the time at our disposal is. I hope the object has been attained, and that you fully realise how well worthy of study is a common living ro t. Not only is it instructive as a simple object of dissection, a subject upon which I have had no time to dwell, but the peculiar properties which stamp it as a living organ themselves afford material for much thought and investigation. When we go further, however, and see how the structure and the functions depend upon one another, some very curious reflections thrust themselves upon us; and if time had allowed us to look at these matters from the other platforms of view—to see how old errors have gradually been explained away on the part of observers, and how what may be called improved adaptations have arisen in the evolution of the root as an organ—these reflections would have obtained in depth. But we have taken a glimpse at matters still more comprehensive: we have touched upon that important question of the relation of the root to its physical environment, and it is not difficult to see numerous points where the struggle must have been intense before the plastic substance of the root was enabled to meet the requirements necessary before it could become a dweller in the land. The evidence of progress and adaptation to its environment on the part of the root is, in fact, so striking and conclusive, that we might take it as a text for a sermon on evolution were such necessary. I have been strongly tempted to occupy some more time with reference to the interesting phenomena shown by roots which cling to trees and walls, &c., or which rob other plants of food-materials; and had time allowed, I would have liked to say a few words about some other adaptations, such as those by means of which roots become pulled up taut in the soil. However, these and other matters cannot be even mentioned, and, indeed, each one deserves a lecture to itself.

FOCAL LINES

WHEN a pencil of light proceeding from a luminous point is incident upon a prism, the rays after refraction do not as a rule diverge from a point, but from two short lines at right angles to each other at some distance apart depending on the angle of incidence of the pencil. These lines are known as the focal lines of the pencil. If the edge of the prism be vertical and the axis of the pencil lie in a horizontal plane, the focal lines are respectively horizontal and vertical. The position of the horizontal line is independent of the angle of incidence of the pencil, its distance from the prism being the same as that of the luminous point, or with the notation of Parkinson's "Optics" (p. 88)—

$$v_2 = u.$$

The distance from the prism of the vertical focal line is, on the other hand, dependent on the angle of incidence, its position being given by the formula—

$$v_1 = \frac{\cos^2\phi' \cos^2\psi}{\cos^2\phi \cos^2\psi'} . u.$$

The image of an object viewed through the prism will appear between the two focal lines, and will be formed by the circles of least confusion. The two focal lines will coincide in position, and they, and the circles of least confusion, will consequently become points if $\phi = \phi'$, that is, if the prism be placed in the position of minimum deviation.

All these phenomena of refraction by a prism, which are of great importance to the spectroscope, may be verified in a very striking manner by using as an object a piece of wire gauze, placed so that one set of wires is horizontal and the other vertical, and illuminated by a sodium flame placed behind it. If the light pass directly from the gauze to the prism, the focal lines are of course virtual, but they may be easily viewed and their positions identified by means of a telescope which will focus an object at a short distance. For one position of the eye-piece of the telescope the vertical wires are seen distinctly while no horizontal wires are seen; whereas for another position the horizontal wires may be focused, but then the vertical ones are no longer visible unless the prism is in the position of minimum deviation. Between these two positions of the eye-piece is a third, for which a blurred image of the gauze is seen corresponding to the circles of least confusion. The positions of the lines may be determined by ascertaining where an object must be placed, when the prism is removed, so as to be in focus in the telescope for the two positions of the eye-piece corresponding to the two focal lines respectively.

The experiment is, however, much more striking if the focal lines be made real by interposing between the gauze and the prism a convex lens of somewhat long focal length. The vertical and horizontal images may then be viewed by means of an ordinary watchmaker's glass, or, better still, by a telescope eye-piece mounted behind a second gauze with its wires set at 45° to the horizon. With this arrangement the images corresponding to the two focal lines can be seen very clearly, and their distances from the prism accurately measured. It is very interesting to place the prism first in the position of minimum deviation, and focus the magnifier upon the image of the gauze, showing both horizontal and vertical wires clearly defined; then on gradually turning the prism the vertical lines disappear completely, leaving a set of horizontal bars across the uniform field, thus verifying the first formula cited above.

If however, the eye-piece be drawn back some way, a badly-defined image of the gauze can be obtained corresponding to the circles of lea t confusion, and, on withdrawing the eye-piece still further, the horizontal lines disappear entirely, while the vertical lines come out sharply defined as a set of vertical bars across a uniform field. As the experiment was arranged here, with a prism of about 9° and the horizontal focal line about two feet from the prism, the distance between the two images was fully six inches when the prism was turned through an angle of about 15° from the position of minimum deviation.

The properties of the focal lines formed by a pencil incident

obliquely upon a lens can be verified in an exactly similar manner. It follows from the formulæ given in Parkinson's "Optics" (p. 101) that, with the usual notation—

$$\frac{u - v_1}{u - v_2} \cdot \frac{v_2}{v_1} = \sec^2\phi.$$

The verification of this formula by the method of observation described above has been found to be a very useful and satisfactory class experiment. W. N. SHAW

Cavendish Laboratory, Cambridge

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The election of Mr. A. Marshall as Professor of Political Economy will be welcomed by all who knew the value of his work when formerly in residence as Lecturer at St. John's College.

The Senate has sanctioned the recommendation that 700*l.* be expended on the purchase of microscopes for the biological classes, on which sum interest at 4 per cent. is to be paid, a small terminal charge being made to the students for the use of the microscopes.

The Botanic Garden Syndicate have recommended the increase of the stipend of the Curator of the Botanic Garden from 150*l.* to 200*l.* The Syndicate have watched with interest the zeal and skill with which Mr. Lynch has applied himself to the conduct and development of the garden. The improvement during his curatorship has been very considerable, in fact remarkable; and the reputation of the garden among botanists and horticulturists, both at home and abroad, has risen so much that it is now considered to hold a place in England second only to the Royal Gardens at Kew. Sir Joseph Hooker has said that the Garden, under Mr. Lynch's able management, is rapidly rising to eminence as one of the very best in Europe. The Syndicate express their strong approval of the assistance which Mr. Lynch's intelligent appreciation of the requirements of botanical teaching has enabled him to render to the University.

DR. GILBERT, Professor of Rural Economy at the University of Oxford, and the associate of Sir J. B. Lawes in the Rothamsted experimental work, has accepted the post of Honorary Professor of Agricultural Chemistry at the Royal Agricultural College, Cirencester, rendered vacant by the death of Dr. Voelcker.

MR. D'ARCY WENTWORTH THOMPSON, B.A., was on Monday elected Professor of Biology, University College, Dundee.

SOCIETIES AND ACADEMIES

LONDON

Physical Society, December 13.—Prof. Guthrie, President, in the chair.—The following communications were read:—On the effect of an electrical current on the rate of thinning of a liquid film, by Profs. A. W. Reinold, F.R.S., and A. W. Rücker, F.R.S., read by Prof. Reinold. In 1877 the authors communicated to the Royal Society an account of some experiments upon the electrical resistance of liquid films. The results then obtained showed that there was some disturbing influence present, and the authors now find this to be the action of the current upon the film itself. The films experimented on were, as in the original experiments, cylindrical and vertical, formed upon two coaxial platinum rings which are the electrodes by which an electric current can enter or leave the film. The mode of formation of these films and the precautions necessary to keep them from gaining or losing moisture by condensation or evaporation have been already described before the Royal Society (*Phil. Trans.*, 1881, part 2). When such a film, just formed, is left to itself, it shows a set of colours of different orders arranged in horizontal bands; as it thins under the action of gravity, these bands gradually broaden out, and descend; a black band soon appears at the top, which likewise extends downwards. If a current is now passed downwards through the film, the motion of the colour-bands is accelerated, showing that the effect of the current is to assist gravity in thinning the film; the black band, however, becomes in part or entirely white. This upon examination is found to be due to the following action; the film is not directly dependent upon the upper ring, but is attached to it by a comparatively thick mass of liquid. The action of the current is to transfer liquid in its own direction, thus, like gravity, thinning the film; the mass of liquid, however, on which the film hangs, by this same action is forced down into the black portion, which consequently becomes white. If the current be passed upwards, the reverse effects occur: the downward motion of the bands is retarded, or, with a strong current, reversed. The explanation is precisely the same as before: the liquid is transferred along the film in the direction of the positive current; it sometimes collects in the form of pendent drops attached to the upper ring; these increase in size, and stream down the sides of the film. Prof. Reinold then formed a plane film between two horizontal wires; the film was illuminated by the lime-light, and its image projected upon a screen; the motion of the bands of colour in the direction of the current produced by fifty Grove's cells was clearly shown.—In a discussion which followed upon the transference of matter with the current, Prof. Ayrton described some experiments recently made by Prof. Perry and himself, which showed that certain metals were carried through mercury in the direction of the current. Mr. Boys remarked upon the apparent inertia of the film; the current seemed to require time to develop its action, no motion of the colour-rings being visible for some seconds after making the current.—Dr. Stone exhibited a tuning-fork interruptor commutator. This is an instrument for reversing an electric current through a circuit a given number of times per second. From the free end of a spring, kept vibrating in unison with an electrically maintained fork, by an electromagnet in the circuit of the fork acting upon an iron armature attached to the spring, project two small aluminium plates, side by side, but insulated by ebonite from the spring and from each other. These are connected by fine wires, which do not interfere with the vibration of the spring, to screws upon the base of the instrument, to which the poles of a battery are joined. The motion of each plate is arrested upwards and downwards by aluminium-stops, so that there are four such stops arranged at the corners of a rectangle. They are connected in pairs diagonally, and each pair is in communication with one end of the external circuit. Thus, when the spring is up, the current flows to the aluminium plates, and is transmitted through the circuit in one direction; when the spring is down, it flows by the lower stops in the opposite direction. The electromotive force is thus reversed in the circuit twice as many times as the fork vibrates per second.—Mr. Lewis Wright exhibited his new oxy hydrogen lantern microscope. Details of this instrument will shortly be published. Geological, medical, and biological specimens were exhibited upon the screen with great distinctness, the definition being singularly perfect under the highest powers.

Anthropological Institute, December 9.—Prof. Flower, F.R.S., President, in the chair.—The election of Miss Müller was announced.—Sir John Lubbock read a paper on marriage customs and relationships among the Australian aborigines. Many tribes are divided into families or gentes, and no man may marry a woman of his own gens. For instance, among the Mount Gambier (South Australia) natives every man is a Kumite or a Kroki, every woman a Kumitegor or a Krokigor. No Kumite may marry a Kumitegor, nor a Kroki a Krokigor. In many cases the divisions are more complex, but the general principle is that no man may marry a woman of the same gens as himself. These divisions often extend through many tribes and over hundreds of miles. But while these restrictions are imposed on marriage, on the other hand, in one sense, every man is considered as a husband of every woman belonging to the gens with which he is permitted to marry; so that, as Messrs. Fison and Howitt forcibly put it, he may have 1000 miles of wives. But though we may call this marriage, and it is a right which in old times was generally, and to a certain extent still is, recognised as perfectly legal and respectable, it does not help us to the origin of marriage in our sense. "Communal marriage" (as he had proposed to call it) was no doubt aboriginal, and founded on natural instincts. But how did the institution of "individual marriage" arise? "Individual marriage" cannot be derived from "communal marriage," because, however much the gentes may be subdivided, the wives must remain in common within the gens. Messrs. Fison and Howitt did not, he thought, sufficiently realise the fundamental distinction between these two customs. They spoke of both as "marriage," and indeed we had no other word for them. Yet they were radically distinct, and even opposite in their characteristics. Sir John Lubbock had suggested, in his work on the "Origin of Civilisation," that, while in such a state of things no man could

appropriate a woman belonging to his own tribe exclusively to himself, still that, if he captured one belonging to another tribe, he thereby acquired an individual and peculiar right to her, and she became his exclusively, no one else having any claim to, or property in, her. He considered that this explained the prevalence of the form of capture in marriage, first pointed out by the late Mr. McLennan in his excellent work on "Primitive Marriage," but which Mr. McLennan attributed to the prevalence of exogamy, or the custom of marrying outside the tribe; while, on the contrary, Sir John Lubbock maintained that individual marriage was founded on capture, because this could alone give a man an exclusive right. This view has recently been contested by Messrs. Fison and Howitt, but Sir John replied in detail to their arguments, and supported his suggestion by strong evidence, some even taken from their own work.—The Director (Mr. Rudler) read a paper on the Jeraeil or initiation ceremonies of the Kurnai tribe, by A. W. Howitt, F.G.S., in which the author gave a detailed account of a Jeraeil at which he himself was present, and drew attention to the manner in which it differs from, or has resemblance to, the Kuringal of the Murring.

EDINBURGH

Royal Society, December 1.—Thos. Stevenson, C.E., President, in the chair.—Mr. Stevenson made some remarks in connection with his election as President.—Sir W. Thomson communicated a paper on the distribution of energy between colliding groups of molecules, in which he drew attention to Boltzmann's extension of a theorem given by Clerk Maxwell for the first time twenty-four years ago. He pointed out that, while Maxwell made his simple theorem the basis of his kinetic theory of gases, Boltzmann's extension would, if true, be fatal to that theory. Prof. Thomson also stated that the proofs of Boltzmann's theorem are not satisfactory. The theorem itself seems improbable, and cannot be accepted unless rigidly demonstrated. He wished to draw the attention of mathematicians to the subject, so that the truth of the theorem might be tested. Prof. Crum Brown remarked that, even in the simplest cases to which the theorem might be applied, there seemed no accordance between its results and actual fact. Prof. Tait stated that the truth of the theorem had seemed to him to be so doubtful that he had called the attention of the Society to it two sessions ago, and had also referred to the matter in his recently-published book on "Heat."—Sir W. Thomson then communicated a paper on the dynamics of reflection and refraction in the wave-theory of light. He gave a complete mathematical theory of reflection and refraction of light supposed to consist of vibrations in homogeneous elastic media of different densities and rigidities in the two substances through which the light was considered to pass. The theory confirmed the views of Stokes, Lorenz, and Rayleigh, that the density of the luminiferous ether is different in different transparent substances, while its effective rigidity is equal.—Sir W. Thomson then gave a paper on Kerr's discovery regarding the reflection of light from a magnetic pole. Kerr's discovery forms an extension of Faraday's observations on the action of magnetism on polarised light passing through transparent substances. The plane of polarisation of light reflected from a polarised magnetic pole is rotated through a definite angle in a direction opposite to the conventional direction of the Amperian current. Some time passed before Kerr's results were obtained by any other observer. Kundt finally succeeded in verifying them, and added the new discovery of the rotation of the plane of polarisation of light passing through a transparent film of iron. In his paper Sir W. Thomson gave a dynamical explanation of these phenomena.—Prof. Tait exhibited a new form of apparatus for determining the compressibility of water. Formerly he measured the compression produced by a given pressure. In his new method he measures the pressure required to produce a given compression. His arrangement allows him to make any number of measurements in rapid succession at any one temperature. Then the temperature can be raised, and corresponding measurements made without once opening the compression-apparatus. Thus experiments which formerly would have taken weeks for their completion could now be accomplished in a single afternoon. Rude results only have been obtained as yet with the old very massive compression-apparatus. These seem to show that the diminution of compressibility at higher pressures becomes less at higher temperatures, and may possibly even become an increase for the first few hundred atmospheres pressure. But no very definite statements can be made till the new, light but strong, apparatus now being made is available for experiment.

PARIS

Academy of Sciences, December 15.—M. Rolland, President, in the chair.—On the forms of the surface of the luminous wave in an isotropic environment situated in a uniform magnetic field: probable existence of a peculiar double refraction in a direction normal to the lines of force, by M. A. Cornu.—On the algebraic relations between the hyper-elliptic functions of the n-order, by M. Brioschi.—On the determination of a special case of isomerism in the acetones, by M. G. Chancel.—On a method of inoculating the large ruminants with the virus of tuberculosis, by M. G. Colin. The experiments made on these animals afford a means of exactly measuring the period of incubation of the tuberculous elements, and determining the time required for the tubercules to pass to the state of transparent granulation.—On the variations of the ozone present in the atmosphere during the late outbreak of cholera in Paris and Marseilles, and on the advantages obtained from ozoneine, by M. Onimus. In both places there was a perceptible diminution of the atmospheric ozone during the prevalence of the epidemic, while a marked difference was observed between the ozonometric condition of the air this year compared with the preceding. In Marseilles the mean for July of this year, when the epidemic was at its height, was 0·86; that for the corresponding period in 1883 as high as 2·17. In Paris the mean for November was 0·44 and 1·82 respectively. The author infers, not that the absence of ozone is the cause of the disorder, but that it is a favourable condition for its development, while it is certain that the presence and persistence of ozone helps materially to arrest its progress. His experiments with Beck's preparation of ozoneine on men and animals were attended with excellent results, and produced no ill effects, even when administered in large doses. Its action affects chiefly the central nervous system, on which it produces a sedative effect, tending to show that this region is the main seat of the malady.—On the theory of the figure of the planets, by M. O. Callandreau.—On a trigonometric formula of interpolation applicable to any values of the independent variable quantity, by M. G. Fouret.—On the sections of mathematical functions, by M. Laguerre.—On the conditions necessary to determine the photometric value of intense foci of light, whether electric or solar, by M. Berthelet.—On some processes of practical spectroscopies, by M. Eug. Demarçay.—On the mutual attraction of bodies in solution and of solid bodies immersed, by M. J. Thoulet. The author shows that, when a salt is dissolved and a solid body immersed in the solution, an attraction is set up between the two substances altogether independent of any chemical action, and that this attraction is in direct proportion to the surface of the solid body.—Note on the dissociation of the hydrate of chlorine, by M. H. Le Chatelier.—Contributions to the study of brucine, by M. Oechsner de Coninck. It is shown that, like cinchonine, brucine contains in its molecule a tetrahydruret of quinoleine. Thus is again confirmed Wischnegradsky's hypothesis that the pyridic and quinolic bases exist in the state of hydrurets in the fixed alkaloids.—On the formation of the shell of the egg of *Scyllium canicula* and *Scyllium catulus*, by M. E. Perravex.—On the biological development of the Chelifer group of Arachnida, by M. Ch. Robin.—On the structure of the digestive apparatus of *Cantharis vesicatoria*, *Epicauta verticalis*, *Lytta fabricii*, *L. atrata*, and some other members of the Cantharides group of insects, by M. Alph. Milne-Edwards.—On the anatomical structure of the peduncles, compared with that of the ordinary axes and of the petioles in plants, by M. E. Laborie.—Account of two specimens of abnormal growth in the mushroom family, by M. Ed. Heckel.—Generic characteristics of Pleuraspidotherium, a mammifer of the Lower Eocene formations from the neighbourhood of Rheims, by M. V. Lemoine.—On the fossils of the Carboniferous strata found in a well recently sunk at Lubière in the Brassac Basin, by M. Grand'Eury.—Note on the periodical recurrence of the crepuscular glows, by M. J. J. Landerer. The recent reappearance of this phenomenon precisely at the same period as last year is regarded by the author as an argument in favour rather of a cosmic than of a volcanic origin.—M. Mascart was elected a member of the Section of Physics, to replace M. Jamin, recently appointed Perpetual Secretary.

BERLIN

Physiological Society, November 14.—Dr. König spoke on colour-blindness. A ray of light decomposed by calc-

spar into two polarised beams perpendicular to each other showed, after passing through a quartz plate, when viewed through a Nicol prism, two halves of different colours in the field of vision of the ocular lens, the colours of these halves varying with the position of the Nicol prism. In the case, however, of a so-called colour-blind or bichromatic eye there was a position of the Nicol prism in which the two different colours in the halves of the field of vision appeared alike. The position in which the colours appeared alike was not always the same, but varied with the thickness of the quartz plate, with the intensity of the light examined, and with the individuality of the bichromatic eye. An instrument of this description was therefore an apparatus that might be depended on for the detection of colour-blindness. Normal eyes, in whatever position the Nicol prism might be held, saw different colours; colour-blind eyes, when the Nicol prism was held in a certain position, saw similar colours. The person whose eyes were to be tested was made to look through the apparatus towards one or other source of light, and if at last, after a greater or less number of turns of the Nicol prism, he saw but one colour, then that person was proved to be colour-blind. The examination of a large number of persons—about fifty—who confounded red and green colours, usually distinguished as red- or green-blind, resulted in showing that, with an equal intensity of light, and with the same apparatus, a part of the colour-blind, on the Nicol prism being placed in a certain position, saw similar colours, while the remainder observed a corresponding similarity of colours with another position of the Nicol prism, this second position producing the same result for all persons of that category. The colour blind being by this means separated into two sharply-defined groups, neither shading into each other nor into the group of normal eyes, it was a matter of much interest to investigate whether these two groups of colour-blind eyes showed any other characteristic peculiarities. Among the methods adopted for determining the colour-blind, that of examining their spectrum, which was said to appear always shortened in different ways in the different cases of the red- and green-blind, was largely applied. It was seen, however, that there were so many particulars to be taken into account as affecting the extent of the spectrum, even in the case of sound eyes, that that method was by no means available for the precise and distinctive measurements here required. Another method, that of determining the neutral point, seemed well adapted for exact physical utilisation. As was known, Young's theory of the perception of colours assumed that in the retina there were three different nerve-elements perceptive of colour: one perceiving red, another green, and the third violet. If the perceptive capacities of each of the nerve-elements were traced as ordinates on the spectrum as abscissæ, three curves would appear, of which the first would have its maximum in red, the second in green, and the third in violet. If all three nerve-elements were acted on with equal force by a stimulus of light, then the sensation of white was produced; but if they were affected in different degrees, then the sensation of partial colour was the result. In the case of the colour-blind there was, according to this theory, one curve wanting, the red, or green, or violet. The two remaining ones, in that case, must now cut each other in one point, and at the spot where this point hit the spectrum, the colour-blind person, his colour-perceptive elements thereby being affected with equal force, must see white: at that spot was the neutral point. The finding of this neutral point by means of a movable slit through which a spectrum could be viewed was, however, attended with several inconveniences prejudicial to precision. Dr. König had therefore constructed a special apparatus for ascertaining the neutral point. [This was described at length by the speaker in his communications to the Physical Society, NATURE, vol. xxix. pp. 168, 496.] In nine persons, some of whom were red, and others green-blind, the neutral points were determined, and the following observations made: (1) The neutral point was able to be measured with great precision in each case of colour-blindness, the average error being at the greatest, 0·4 millionth of a millimetre, wave-length, and in the least 0·1 millionth of a millimetre. (2) The neutral point in the case of all colour-blind persons, green- as well as red-blind, was situated at one spot of the spectrum, in the green blue, between the wave-lengths 492 and 505 millionths of a millimetre. A division of the colour-blind into two groups, such as could be so exactly carried out with the leucoscope, was, however, not possible through determinations of the neutral point, for on the leucoscope colour-blind persons of different descriptions had their neutral points quite close to each other, while eyes leucoscopically alike had their neutral points most remote from each other. (3) With increasing intensity of light the neutral point was displaced in all cases of colour-blindness towards the more refrangible end of the spectrum. Among the results of the measurements referred to, that cited under (2) was of extreme interest for the theory of colour-blindness. One conclusion it yielded was that the idea of the nature of colour-blindness derived from Young's theory received no support from the experimental examination of the consequences deduced from it. Dr. König had occasion quite recently to examine a so-called violet-blind person, and another who was totally colour-blind, but he had not yet had time to reduce the measurements he had carried out respecting these two cases, and would therefore reserve further particulars of them to another opportunity. The fact established in (1), that with the apparatus constructed for ascertaining the neutral point separate small sections of the spectrum may be so sharply marked off and determined according to their undulatory length, induced Dr. König to make use of this apparatus for investigations respecting the colour-perceiving capacities of normal eyes. In co-operation with Dr. Dietrici he had first examined the degree of sensitiveness to distinctions of colour in the different parts of the spectrum between 650 and 430 millionths of a millimetre, undulatory length, and gave a summary of the results thereby obtained which he had already communicated to the Physical Society (NATURE, xxix. 496, xxx. 308). It deserved here, however, to be brought prominently forward that the maximum of colour-sensibility of the two normal eyes coincided with that spot of the spectrum at which the neutral point occurred in the colour-blind, and that this maximum of colour-sensibility shifted, in the same way as the neutral point, with increase of the intensity of light towards the blue end. The further investigations contemplated by Dr. König relate to the colour sensibility beyond the wave-lengths 650 and 430 millionths of a millimetre, and determinations in regard to colour-contrast.

THE "AMERICAN JOURNAL OF MATHEMATICS"

American Journal of Mathematics, Pure and Applied. Published under the Auspices of the Johns Hopkins University. Vols. v., vi., vii., Part I. (Baltimore: Isaac Friedenwald, 1882-4.)

THE general features of this *Journal* have been clearly indicated in the notices of the previous volumes (see NATURE, vol. xxii. p. 73, vol. xxvii. p. 193), and we need only remark under this head that these original characteristics have been maintained throughout the numbers now under our consideration.

Prof. Sylvester was the editor-in-chief until his return to this country; now the mantle has fallen upon his successor, Prof. Newcomb, under whose auspices vol. vii. is being published. Dr. Thomas Craig has been the assistant editor during the issue of all the numbers.

The chief papers treat of the higher algebra. In this branch the contributions of Prof. Sylvester naturally loom large. They are "On Sub-Invariants, *i.e.* Semi-Invariants to Binary Quantics of an Unlimited Order," "Tables of Generating Functions, reduced and representative for certain Ternary Systems of Binary Forms" (the "Tables" were calculated by Messrs. Durfee and Ely), "A Constructive Theory of Partitions, arranged in Three Acts, an Interact, and an Exodion," a most valuable contribution to the theory, written with the author's characteristic fervour, but perhaps the gem of the collection is the first instalment of the "Lectures on the Principles of Universal Algebra."

We naturally turn next to the papers by Prof. Cayley. These are a "Note on a Partition-Series," "A Memoir on Seminvariants," following up a "remarkable" discovery by Capt. Macmahon, which leads to the conclusion that the theory of seminvariants is a part of that of symmetric functions, and three sets of tables, viz. non-unitary partition tables, seminvariant tables, and tables of the symmetric functions of the roots, to the degree 10 for the form—

$$1 + bx + cx^2/1 \cdot 2 + \ldots = (1 - \alpha x)(1 - \beta x)(1 - \gamma x) \ldots$$

Following in the wake of these leviathans, Mr. Durfee contributes "Tables of the Symmetric Functions of the Twelfthic," and "The Tabulation of Symmetric Functions"; Capt. Macmahon writes on "Seminvariants and Symmetric Functions," "Symmetric Functions of the 13^{ic}," and "On Perpetuants"; he is also the author of a short "Note on the Development of an Algebraic Fraction," the moving cause of which is a previous article by M. Faà de Bruno, entitled "Sur le développement des fonctions rationnelles," which in its turn owed its origin to a note by Prof. Sylvester in the *Johns Hopkins Circulars.* Mr. J. Hammond, another worker in this field, has a paper "On the Solution of the Differential Equation of Sources," in which he gives a disproof of Prof. Sylvester's fundamental postulate, a discovery which he first communicated to the London Mathematical Society. Mr. G. S. Ely applies the method of graphs to compound partitions, and Mr. Morgan Jenkins gives a proof of a theorem in partitions, and furnishes a note on Prof. Sylvester's constructive theory of partitions, mentioned above.

We pass from this group of subjects, which centres more especially round the name of Sylvester, and come to papers on elliptic functions in one or other of the forms under which that branch is now ranged. M. Faà de Bruno has a long article on "Quelques applications de la théorie des formes binaires aux fonctions elliptiques"; Dr. Craig contributes several papers, viz. "Some Elliptic Function Formulæ," "On a Theta-Function Formula," "On Quadruple Theta-Functions" (two papers), "On Theta-Functions with Complex Characteristics," and "On Certain Groups of Relations satisfied by the Quadruple Theta-Functions." Prof. W. W. Johnson presents a proof of the imaginary period in elliptic functions; Mr. A. L Daniels communicates three notes on Weierstrass's methods in the theory of these functions; and Prof. Cayley, in a memoir on the abelian and theta functions, reproduces, with additional developments, the course of lectures which he delivered at the Johns Hopkins University in the early months of 1882.

The other papers on algebraical subjects may be grouped together. They are:—"On Division of Series," by Rev. J. Hagen; "Tables for Facilitating the Determination of Empirical Formulæ," by A. W. Hale; "On the Development of an Algebraic Fraction," by Dr. Franklin; some papers "On the Theory of Numbers," by A. S. Hathaway; "Sur une formule relative à la théorie des fonctions d'une variable," by M. Hermite; "Calculus of Direction and Position," by E. W. Hyde; "Compound Determinants," by C. A. Van Velzer (written before the author had seen Mr. R. F. Scott's paper in vol. xiv. of the London Mathematical Society's *Proceedings*), in which is discussed Picquet's proof of a theorem of Sylvester's. Mr. McClintock writes on the resolutions of equations of the fifth degree, a subject which is also handled by Mr. G. P. Young, who in addition discusses the principles of the solution of equations of the higher degrees. Mr. G. S. Ely furnishes some notes on the numbers of Bernouilli and Euler (adopting a name given by Sylvester), and gives a useful bibliography of Bernouilli's numbers. Such lists as these are of great service to workers.

Dr. Story defines the absolute classification of loci to be that classification which is not altered by any real linear transformation, and which is identical with the ordinary classification in so far as the latter is independent of all consideration of the nature of the infinite elements of the loci; a part of this classification has been made (as Dr. Story remarks) in essence by Prof. Sylvester in the *Phil. Mag.* (February 1851). The title of the paper is "On the Absolute Classification of Quadratic Loci, and on their Intersections with each other and with Linear Loci." The same author also contributes two articles on the non-Euclidian geometry: one is a continuation of a paper by him in vol. iv., and in it are given a number of formulæ relating to distances, angles, areas, and volumes; the other is entitled "Non-Euclidian Properties of Conics," and contains an application of Prof. Cayley's projective measurement, generalised by Klein, and still further extended by the author in the paper just cited, to the conic.

Dr. Franklin discusses some points in the theory of

cubic curves by a novel method, but not many new theorems are the result; and Mr. E. W. Davis gives an expression for the co-ordinates of a point on a binodal quartic curve as rational functions of the elliptic functions of a variable parameter.

The only purely geometrical article is one by Mr. B. Alvord, entitled "The Intersection of Circles and the Intersection of Spheres." The problems discussed are to draw a circle which shall make a given angle with three given circles; to draw a sphere which shall cut each of four given spheres at a given angle; and then two Steinerian problems, viz. to draw a circle which shall cut four given circles at the same angle (angle unknown), and the analogous problem for five spheres. The number of solutions in each case is given, and there are four plates containing thirteen figures. Prof. C. H. Smith supplies a graphic method of solving spherical triangles.

There is a single astronomical article on certain possible abbreviations in the computation of the long-period inequalities of the moon's motion due to the direct action of the planets, by Mr. G. W. Hill, who states that Hansen has characterised the calculation of the coefficients of these inequalities as extremely difficult, but he himself thinks that, if the shortest methods are followed, there is no ground for such an assertion.

Prof. Turazza gives a note (which the editor had mislaid for three years), "Di un nuovo teorema relativo alla rotazione di un corpo ad un asse."

The only physical paper is Prof. Rowland's, "On the Propagation of an Arbitrary Electro-magnetic Disturbance on Spherical Waves of Light and the Dynamical Theory of Diffraction." The classical paper by Stokes "On the Dynamical Theory of Diffraction" is discussed; in addition the author treats of the general problem of spherical waves of light, which he has not seen considered anywhere else.

We think the titles of the papers and a perusal of their contents quite bear out Mr. Glaisher's opinion, pronounced in his notice of the previous volumes (vol. xxvii. *ubi supra*), viz. that "the volumes represent a considerable amount of mathematical work, a fair proportion of which may have real influence on the advancement of the science." Some readers might like to have a more diversified bill of fare set before them, but no one can say that what is offered is not generally first class. The form of the *Journal* lends itself admirably to the important tables with which it has been enriched from its earliest days. We are glad to find this young work maintaining its early promise, and we wish for it even a higher success in the days to come.

A SYSTEM OF PSYCHOLOGY

A System of Psychology. By Daniel Greenleaf Thompson. 2 vols. (London: Longmans, 1884.)

PSYCHOLOGY, like other sciences, may be regarded as a pure science, or as a set of generalisations capable of application to practice, or as material for a philosophical construction. Mr. Thompson has treated it, for the most part, in the spirit of a scientific inquirer. He does not stop to make applications to practical questions, and although he is not without metaphysical views of his own, it is evident that he is interested in psychology more for its own sake than for the sake of its bearing on his theory of the universe. There is, therefore, no need to discuss here the questions in dispute between the empirical school to which Mr. Thompson belongs and its various critics. As he has treated psychology so much in the scientific spirit, we may confine ourselves to indicating the kind of work he has done in his own special line.

Some have denied that psychology is a science, on the ground that it does not make progress; but it is only necessary to compare Locke's "Essay" with any modern work in which the treatment is not altogether inadequate, in order to see that progress has been made both in accuracy of description and in refinement of analysis of psychological facts. The admiration that must be felt for what Locke was able to do only makes the comparison more conclusive so far as the establishment of the scientific character of psychology is concerned. In criticising any new book, then, we ought to ask whether the author has made any advance on his immediate predecessors. We ought, in fact, to apply to the particular author we are criticising the test of progress to which psychology as a whole may be submitted. Mr. Thompson's book will emerge successfully from an examination such as that which is here suggested. In dealing with many special questions he goes beyond the later English psychologists just as they themselves have gone beyond Locke.

A student might very well begin with the sixth part of Mr. Thompson's book, entitled "The General Development of States of Consciousness," in order to get at the author's more important results, and then read the parts that come before it to understand more fully his general view of his subject, and the parts that come after it for new details. In this division of his work, the author brings out very clearly the difference between "presentative" and "representative" states of consciousness, and shows the influence of this difference in the spheres of feeling and of will, as well as of cognition. Emotional states are classified according to their relation to the environment, which may take the form of "pleasurable interest in external objects" or of "aversion to external objects." The chapter on "volitional development" (the first of the second volume) deserves the special attention of the psychological student. Mr. Thompson's introduction into the view he gives of the external world in its relation to mind (in Part III.), of a sort of Cartesian conception of "matter" as including "space," must be at least alluded to as likely to be found interesting both by physicists and metaphysicians. Although philosophy and science are now too much specialised for an idea of this kind to have any direct influence on research, yet all discussion between philosophers and men of science of the more general terminology of the sciences, and especially of physics, must have some effect in compelling clear definition of terms on the part of physicists and at the same time in keeping philosophic thought in contact with its basis of scientific law.

Mr. Thompson might perhaps have given a better account of the introspective method in psychology if he had had fuller possession of the idea of mind as something common to all individuals; if he had been able to show more clearly that it is not simply the individual

mind, but rather the general human mind, that the psychologist analyses. His omission to make it clear that psychology is really the science of human nature, and not a mere description of the mental states of an individual, or of as many individuals as possible, does not, however, destroy the value of his results. When he describes the science of psychology as being a sort of resultant of the contributions of various people who "chronicle their states," this is only an imperfect description of the method of psychology and of what it implies. To state the case in this way is to lose sight of the fact that society is an organism, and to consider it as an aggregate of isolated individuals; but, without any elaborate analysis, we may show that the introspective method of Mr. Thompson and of the older psychologists really implies more than the examination of any number of individual minds merely as such.

There is probably quite as much minute observation of mental states to be found in literature with no scientific pretensions,—in novels and autobiographies, for example, —as in books of psychology. Why has this kind of "introspection" first of all a literary, and only secondarily a scientific, interest? Is it not because the states of mind described are regarded as states of a particular mind, because they are merely elements in the description of some one personality, because they have no distinct reference to a law of mind in general? Of course some things in books of psychology have only a personal interest, and some things in books of pure literature may have a scientific interest; but there is no difficulty in distinguishing the two kinds of "introspection" when we meet with them, or in recognising them as essentially different.

The scientific character of the introspective method as being one that yields general conclusions is quite evident in Mr. Thompson's book, in spite of his omission definitely to point out this character. It has already been said that his "System of Psychology" furnishes new evidence of the progressive character of psychological studies. We may conclude by saying that, although in some respects an unequal book, it is decidedly an important contribution of America to the treatment of psychology on the lines with which English readers are most familiar.

OUR BOOK SHELF

The Student's Flora of the British Islands. By Sir J. D. Hooker, K.C.B., &c., &c. Third Edition. (London: Macmillan and Co., 1884.)

THE lover and collector of our wild plants may congratulate himself on the number of botanists of the first rank who have devoted their energies to his service. Bentham, Hooker, and Babington have all of them written hand-books of the British flora, all of them excellent in their way. In the one now before us we have the well-known lucidity of description characteristic of the author combined with the most recent extensions of our knowledge as regards British plants. Very great care and labour have been expended in bringing the "Student's Flora" abreast of the most recent discoveries. The number of species of flowering-plants added to the British flora since the publication of the last edition in 1878 is not inconsiderable, indeed is surprising, considering the limited extent of the field and the number of workers on it. In addition to the introduction of these new species, the limits of species and sub-species have been carefully revised, and the "critical" genera submitted to the criticism of experts; the genus *Potamogeton* having been, in particular, revised by Mr. Arthur Bennett. Nor has the physiological side of the subject been neglected. For the first time, as far as I am aware, in any local flora of importance, the characters of the genera concerned in the process of fertilisation are given, especially those illustrated by the writings of the late Hermann Müller. Under the diagnosis of each genus it is stated—as far as is known —whether the plants belonging to it are wind-fertilised, insect-fertilised, or self-fertilised; whether honey is secreted in the flower or not; and whether the stamens and stigma ripen together, or, if not, which is the earlier. The result is that the field-student has now a hand-book of the characters of the plants that he meets with in wood and field, by stream and bog, and on the mountain-side, more complete than any which has heretofore been ready to his hand.

A. W. B.

Elementary Text-Book of Zoology. General Part and Special Part, Protozoa to Insectă. By Dr. C. Claus. Translated and edited by Adam Sedgwick, M.A., Fellow and Lecturer of Trinity College, Cambridge, with the assistance of F. G. Heathcote, B.A., Trinity College, Cambridge. (London: W. Swan Sonnenschein and Co., 1884.)

PROF. CLAUS'S "Elementary Text-Book of Zoology" has long been known as an excellent introduction to this branch of biology, and there was a certain charm in the way in which the introductory chapters, constituting the "General Part" of the work were written, that marked out the "Lehrbuch der Zoologie" as something different from many of the text-books that had preceded it. Its well-merited success in parts of the Continent where German is spoken is a matter of congratulation, and Mr. Sedgwick has translated it "with a view of supplying the want which," he tells us, "has long been felt by teachers as well as students in this country, of a good elementary text-book of zoology." It appears to us a pity that with this local demand for a good introduction to zoology, there should be apparently no other way of supplying it than by translating the works of our illustrious neighbours. It is certainly not the way that the schools of the great Continental centres are supplied, nor do we believe that it is from any want of original power to supply the need among our own zoologists. This view of the subject apart, the English student of zoology will find this translation of Claus's "Lehrbuch" a very excellent introduction. It is true that he may now and then note that it was not written for him, that the illustrations of specific forms referred to are not always, even when they might have been, within his easy reach; that some of the contributions of his countrymen are referred to as if they had first appeared in a foreign tongue, and that many very important ones are overlooked, but these will be scarcely difficulties in his way; and if they are, on application to an intelligent teacher they will be soon got over.

The original German has, with a few "unimportant exceptions, been closely followed throughout," but has it not been too closely adhered to, when it has been left altogether untranslated, as it apparently has been in the case of many very familiar families of insects? In some of these, too, the English equivalents are not perhaps of the best; thus Acanthiadæ (skin-bugs). In welcoming this attempt to introduce Prof. Claus's most useful work to the English reader we have no wish in any way to criticise the treatise in detail. It is got up in a very creditable manner, though a little more uniformity in the style of printing the technical words would have been desirable; thus, on the same page we find the words "Cirripedia" and "Malacostraca" in roman and in italic type, and specific names are not italicised in all cases,

while sometimes such English words as "insect," "spider," "scorpion" will be in one form of type, and sometimes in another. These are trifles, but still they are worth attending to, and they do not detract from the general merit of this translation, which we would freely place in the hand of any student.

Bosnien, Land und Leute. By Adolf Strausz. 2 vols. (Vienna, 1882-4.)

AFTER the occupation of Bosnia and Herzegovina by Austria in 1878, the want of an authoritative and comprehensive treatise on those hitherto neglected provinces of European Turkey soon became manifest. This want is fully supplied by the present work, on which the author has been engaged for the last four years, and for the composition of which he has qualified himself by repeated visits to the region he has undertaken to describe. The first volume, issued two years ago, is mainly historical and ethnographic, and embodies a complete history of the country, from the arrival of the Slavs in the fifth century, down to the Austrian occupation in 1878. Special sections are devoted to the various ethnical elements, Mohammedan and Christian Bosnians, Jews, Albanians, Zinzars, and Gypsies. These are all adequately treated, except the Zinzars (Macedo-Roumanians or Kutzo-Vlacks), the account of whom is confusing and even contradictory. The author seems unaware that their true relations to the surrounding populations, and especially to the Roumanians, now settled in Moldavia and Wallachia, north of the Danube, have been placed in a clear light by the recent investigations, especially of Roesler and P. Hunfalvy. The volume concludes with a series of social sketches, in which the habits and customs, legends, traditions, religions, national aspirations of the people are ably dealt with. The second volume, whose publication was delayed by various causes till the present year, is perhaps the more important of the two. It contains a complete description of the provinces, their geographical features, climate, fauna, flora, natural and industrial resources, administration, present condition and future prospects. On all these points the author speaks with great authority, and brings together a vast amount of information at first hand. Although bitterly opposed to the Austrian occupation, he believes that the inhabitants will eventually acquiesce in a step which political considerations had in any case rendered inevitable. The area of the country is given at about 52,000 square kilometres, an estimate based on recent but still incomplete surveys. The population, given by the Salname of 1877 at 2,047,000, was reduced by the census of 1879 to 1,158,000, of whom 448,000 were Mohammedans, 496,000 Orthodox Greeks, 209,000 Roman Catholics of the Latin rite, and 3400 Jews. The work unfortunately appears without either map or index, for which two meagre tables of contents are poor compensation.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Solar Corona and After-Glow

THE inclosed extract from a letter from the Rev. A. W. Heyde, resident at Kailang in Lahoul, a hill state in the North-West Himalaya (N. lat. 32° 34′ 10″, E. long. 77° 4′ 10″), 10,000 feet above sea-level, gives an interesting notice of the solar corona and after-glow, and affords some reason for the inference that the conditions producing these appearances have been persistent, although they may not have been observed in the cloudier and more hazy atmosphere over the plains of India. Mr. Heyde's letter is dated November 3:—

"The corona round the sun has been visible since my last letter to you in July, whenever the sky was clear. It was not always equally distinct, but never entirely absent. It is beautifully distinct to-day. The same has been the case with the after-glow, which no doubt results from [the same conditions as] the corona."

The following extract from the same letter is also of interest:—

"I think I have mentioned already, in former letters to you, that since about twelve or fifteen years the latter half of August and the whole of September and October have become very unsettled as regards the weather, rain or snow occurring now often during these months, which, as a rule formerly, were a time of fine, clear weather. These untimely precipitations interfere very unpleasantly with the haymaking and harvesting in the valley now nearly every year, of which many complaints are heard. . . . A similar experience is made in Ladak and other parts of the Western Himalayas. Officers who took part in the triangulation of Ladak during the four or five seasons between 1860 and 1870 say they never could have done their work if at that time the sky over Ladak had always been so cloudy, and the high ranges so frequently enveloped in clouds, as is now the case."

In corroboration of this last remark I may mention that the hopes that had been entertained of obtaining a valuable series of actinometric observations at Leh, for which purpose two trained observers were deputed to that station rather more than a twelvemonth ago, have been so far grievously disappointed. The atmosphere of Leh was believed, on the reiterated assurance of former residents, to be remarkable for its clearness and freedom from cloud and haze. From the actinometric registers received during the past year, and the notes which accompany them, this appears to be very far from the case.

HENRY F. BLANFORD

Meteorological Office, India, 4, Middleton Row, Calcutta, November 21, 1884

Flying-Fish do not Fly

FLYING-FISH *are incapable of flying* for the simple reason that the muscles of their pectoral fins are not large enough to bear the weight of their body aloft in the air. The pectoral muscles of birds depressing their wings weigh, on an average, $\frac{1}{6}$ of the total weight of the body, the pectoral muscles of bats $\frac{1}{13}$, the muscles of the pectoral fins of flying-fish only $\frac{1}{32}$. The impulse to which flying-fish owe their long shooting passage through the air is delivered, while they are still in the water, by the powerful masses of muscle on both sides of their body, which are of much greater breadth than in the case of the herring or any other fish of their own size.

The "flickering of the fins," which Dr. John Rae (NATURE, December 4, p. 102), like many others before him, takes for a rapid muscular movement of the pectoral fins, is only a vibration of their elastic membrane, and is to be referred to the same laws as those which govern the flapping of a tight-set sail when a ship under a stiff breeze is driving close to the wind. The flapping or vibration at once springs up whenever the sail gets parallel to the wind.

The more rapidly a flying-fish darts out of the water, the greater is the momentum with which the air presses on its outspread pectoral fins. Should, now, the atmospheric pressure induce these fins into a horizontal position parallel to the wind, their vibration is a necessary result. Let the outspread pectoral fins of a dead flying-fish be held horizontally before the opening of a pair of bellows, and the fins will be seen to vibrate as soon as the current of air passes under them. For full proofs of the accuracy of these propositions I beg to refer to my paper, "The Movements of Flying-Fish through the Air" (Leipzig, 1878).

Zoological Institut, Kiel, Dec. 15, 1884 K. MÖBIUS

Iridescent Clouds

IN addition to the particulars given in NATURE for December 18, 1884 (p. 148) of the brilliantly-coloured clouds, the following observations made here may be interesting. They were visible every day from the 6th to the 13th instant, except it be on the 9th, and at all times of the day, but only strikingly noticeable near sunrise and sunset. The colours did not appear

on them when they were very far from the sun, they then being simply white. I did not see any dark ones, as described by J. E. Clark; indeed they always struck me as being very thin, merely like a nearly flat sheet. They tended to be arranged in bands like "Noah's Arks," and, while their texture was smoother than most cirrus clouds, they were more or less striated transversely. On some afternoons I noticed in many cases a feeble smoke-like prolongation, or tail, on the east side of the cloud; this had no colouring. They had thus sometimes a striking resemblance to an aurora, differing essentially, however, in their real position being horizontal, while the auroral band and rays are almost vertical. Their direction also was quite different: on the 11th at 8·15 a.m., and 13th at 3·40 p.m. I noticed that the striæ pointed to east by south. In shape they approached parallelograms apparently; really, to rectangles; sometimes they were very perfect rectangles. One of the most striking clouds was, however, a perfect right-angled triangle in form. Their motion was very slow. Some time after sunset they were so bright as to give a material amount of light, and to make the dust-circle around the sun look quite dim. They were evidently at a great height, though they looked lower than the dust-wisps. They were incapable of producing an ordinary halo.

Like Prof. C. Piazzi-Smyth, I can say that I have no recollection of seeing any clouds of the kind before. I saw nothing like them at the time of the grand sunsets last autumn, and I think he is mistaken in supposing any of the phenomena then seen were of the same character. T. W. BACKHOUSE

Sunderland, December 22, 1884

REFERRING to the letters which have appeared in these columns on the subject of "Iridescent Clouds" as seen at Edinburgh and York on the evening of December 11, a very similar phenomenon was seen at Derby at sunrise on that day, and was thus described in the *Derby Express* the same evening:—"About half an hour before sunrise the eastern half of the sky was covered with a dense pallium of cirrus cloud. About 30° above the horizon was seen what appeared to be an elongated opening in the dark grey of the cloud. Through this spindle-shaped opening the sky was of an intense emerald colour. The strangest part of the phenomenon, however, occurred shortly before eight o'clock, when the vivid green had given place to a mass of brightness comprising all the prismatic colours arranged in bands transversely, each of the primary colours shading gradually into its neighbour in the same manner as in a solar rainbow. The appearance was now not unlike a huge many-coloured eye set in a dark uniformity of cirro-stratus. As the sun arose the colouring faded, and when the solar orb was several degrees above the horizon the phenomenon remained as a patch of brightness upon a silver-grey vapour, and was somewhat similar in appearance to an imperfectly formed parhelion. Its position, however, with regard to the true sun, showed at once that the phenomenon was not of the parhelion class"

C. J. P.

THE iridescent cloud effect mentioned by your correspondents (see NATURE, p. 148) was well seen here on the 13th about 4 p.m., and was very much as described by Mr. Clark. Three distinct bands of colour were seen just at the upper edge of a dark slate-coloured cloud towards south-west, and two faint ones on the clearer sky above. I write specially to remark on the nature of the colour of these bands. They were not *prismatic* colours as mentioned by Mr. Clark, but unmistakable *interference* or residual colours, the lowest bright purplish pink, shading into green, the next the peculiar light brick red seen in Newton's rings, and a very recognisable colour, also shading into green, and the rest pink and green, of similar colour to the lowest. There can be, I think, no question that this was an interference-phenomenon, and I hope some of your correspondents may be able to give the *rationale* of it.

Fairfield House, Darlington JAMES I'ANSON

I SEE notes in NATURE, December 18, 1884 (p. 148), on iridescent clouds. I observed similar appearances on the Yorkshire Wolds, between Market Weighton and Brough, on December 6 and again on December 13, 3-4 p.m.; but instead of the clouds being totally coloured, only the edges of rifts in a thick cloud-mass were so tinged. The phenomenon was much finer on the latter date, the rift being much larger and the colours more widely dispersed at one end, so that a rose tinge occupied there the whole of the acute angle of the gap.

Broseley, Shropshire W. W. WATTS

The Rotation of Neptune

SEVERAL circumstances delayed my observation of the planet Neptune this autumn until November 24. On that and the two following nights the light of Neptune was compared with the light of the star B.A.C. 1072; and, assuming that the light of the star was steady, that of Neptune was found to undergo apparently regular variations, but much smaller than they were last year.

The observations were combined in the following manner:—The magnitude, m, at any time, t, was assumed equal to

$$m_o + k \sin n (t - t_o),$$

where m_o was the mean magnitude at the time t_o, k one-half the variation between maximum and minimum, and n equal to $\frac{360^\circ}{7·92}$, or 45°·45, according to the observations of Neptune last year, which gave 7·92 h. as the rotation-period. Subtracting m', the unknown magnitude of the comparison star, which is, however, of about the seventh magnitude, we have

$$m - m' = m_o - m' + k \sin n (t - t_o);$$

and by assuming approximate values, by introducing corrections, and by solving the 11 equations corresponding to the 11 observations by the method of least squares, it was found that

$$m_o - m' = 0·86$$
$$k = 0·19$$
$$t_o = \text{Nov. 24d. 13·01h. G.M.T.}$$

The preceding epoch of maximum will be found by subtracting 1·98h.; and similarly the following epoch of minimum will be found by adding 1·98h.

Now these observations were made without special care, and consequently the probable errors were larger than they should be in comparison with the small variation; but on the night of November 29 every care was taken to obtain accuracy in the photometric measures, and the following results were obtained:—

$$m_o - m' = 0·82$$
$$k = 0·20$$
$$t_o = \text{Nov. 29d. 11·72h. G.M.T.}$$

The following is the comparison of observation and computation:—

Kempshot M.T. 1884 Nov. 29 h. m.	Diff. mag. ($m - m'$) Obs.	Comp.	o − C.
7 10	0·91	0·92	−0·01
8 26	1·03	1·02	+0·01
10 5	0·88	0·88	0·00
12 7	0·64	0·63	+0·01

It should perhaps be added that Kempshot is 5·19h. west of Greenwich.

By comparing the epoch on November 29 with the corresponding epoch on November 24, we find that 15 rotation-periods occupy 118·71h., so that each rotation-period is 7·914h., which may be considered identical with the period found last year. MAXWELL HALL

Jamaica, December 1, 1884

Peculiar Ice-Forms

CIRCUMSTANCES have prevented my replying earlier to Dr. Rae's letter in NATURE of November 27 (p. 81). The situation of the ice described in my letter of November 6 (p. 5) precludes the possibility of its having been a remainder from last winter's snow, since it was only some fifteen hundred feet above the valley of Chamounix, and exposed during the summer months to daily sunshine. In fact, the mid-day sun only just failed to reach it on the 17th of October.

In the *Neues Jahrbuch für Mineralogie* for 1877 (referred to by Dr. Wetterhan of Freiburg in NATURE, vol. xxi. p. 396) is an article by Dr. G. A. Koch giving an elaborate description and discussion of a very similar ice-structure, formed under very similar circumstances, which he observed on October 18, 1875, near St. Anton in the Arlberg. He also quotes other cases observed on the Wormserjoch in the Tyrol, and by Prof. Doenitz

in Japan. In all these, as well as in the case of the hills near Freiburg mentioned by Dr. Wetterhan, the soil appears to be a porous detritus with a hard substratum. At St. Anton, as at Chamounix, the hill-side sloped at an angle of about 50°, with a northern aspect, and in both cases and in Japan the phenomenon occurred in the autumn, a season often characterised, especially at high elevations, by cold nights and genial days. Dr. Koch calls it "*sonderbar*" and "*ganz eigenthümlich*," and it is plainly not of common occurrence.

Dr. Koch's explanation of the phenomenon is virtually the same as had occurred to me, except that both he and Dr. Wetterhan appear to consider that the water was derived by absorption from a moist atmosphere. In none of the descriptions, however, is there any mention of what was one of the most striking features of the ice which I tried to describe, viz. its division into distinct layers, each layer being of uniform depth; and this, showing as it does that the crystallisation was interrupted, and not continuous, seems to make it more probable that the water was supplied from below. The cylindrical perforations were, no doubt, caused by the presence of pebbles or small lumps of earth too dense to allow the ice-crystals to penetrate them, and too heavy to be pushed up. The layer of dust on the surface was much thinner in my case than in Dr. Koch's, which was no doubt due to accidental difference in the soil.

A friend in the country tells me that on a bright winter's day two or three years ago he picked up a piece of a dead beech-branch which was covered with filamentous ice, such as is described by the Duke of Argyll and others in NATURE (vol. xxi. pp. 274, 302). He brought it home, and, having examined it, left it out in the sun, when the crystals of course soon vanished. Next morning, however, he was surprised to see that they had all reappeared as before. The water from the melting ice had again filled the pores of the wood, and again been extruded in the same crystalline form. Now, if the highest temperature to which they had been exposed during the day had been 32° F., and a fresh supply of water had been afforded from any source to the wood, then neither would the ice have melted nor the water frozen; until the temperature fell again at night, when a fresh formation of crystals would have taken place, which would have pushed up those previously existing, and the result would have been a formation similar to that described in my letter. It seems more probable, therefore, that the moistening took place from below, as I suggested.

Hampstead, December 20, 1884 B. WOODD SMITH

Lightning in the Tropics

MY experience confirms the remarks of Dr. Von Danckelman in NATURE (p. 127) respecting the little damage done by lightning in tropical climates.

In the plains of India at the commencement of the monsoon, storms occur in which the lightning runs like snakes all over the sky at the rate of three or four flashes in a second, and the thunder roars without a break for, frequently, one or two hours at a time. During twelve years' residence in India I heard of only two human beings and, I think, three buildings being struck, although in parts of Lower Bengal the population amounts to more than 600 to the square mile. I always attributed the scarcity of accidents to the great depth of the stratum of heated air next the ground keeping the clouds at such a height that most of the flashes pass from cloud to cloud, and very few reach the earth. This idea is supported by the fact that in the Himalayas, at 6000 feet or more above the sea, buildings and trees are frequently struck. I have seen more than a dozen pine-trees which had been injured by lightning on the top of one mountain between 8000 and 9000 feet high. In the British Islands thunderstorms are said to be more dangerous in winter than in summer, and such a fact, if true, can be explained by the very thin stratum of air then intervening between the clouds and earth. J. J. MEYRICK

London, December 19, 1884

An Unnoticed Factor in Evolution

I AM surprised that the letter of Mr. Catchpool in NATURE (vol. xxxi. p. 4) has remained unnoticed by your correspondents. His hypothesis that mutual sterility may be the *cause*, not the *result*, of specific divergence, is, I think, quite in accordance with many observed facts. The buffalo and the ox, the sheep and the goat, have lived for ages side by side without, as far as I am aware, a hybrid between either of them having been produced. Mule or hinny hybrids between the horse and the ass are obtained easily, but the offspring is rarely fertile, so rare, that the British Consul at Granada told me, when I was there, that he had never known of a case, although in Spain mules exist in thousands. Amongst bovine animals many species produce hybrids which are apparently perfectly fertile; those between the Indian ox and the gayal, species of different genera, *Bos* and *Bibos*, are common, and their fertility is shown by the existence of numerous intermediate hybrids. There is living at the Zoological Gardens at the present time, a hybrid between the Indian ox, the gayal, and the bison, and, by her side, a hybrid between herself and a bison. The offspring of the cross between many species of ducks are perfectly fertile. This I have repeatedly seen in the case of the hybrids between the tufted duck and the pochard. I think there is another *unnoticed factor in evolution*. The scent of animals plays an important part in their sexual relationships, and "sports" in this respect are as likely to occur as in the organs of the body; thus the peculiar odours of the sheep and the goat may be mutually repulsive. J. JENNER WEIR

Chirbury, Beckenham, Kent, December 15, 1884

A Large Meteor

A MAGNIFICENT meteor was observed here last night. Its path lay from the west of σ Hydræ towards the west of η Monocerotis. Its head could not exactly be said to explode but broke up and extended suddenly considerably along its course, emitting a deep red and bluish white light, the latter of a most extraordinary brightness, for a moment quite sufficient to allow print to be discerned. It disappeared very near 11h. 19m. 6s. M.T. Dublin, and left a bluish white trace behind it, which could still with certainty be perceived seventeen minutes after the meteor had disappeared. OTTO BOEDDICKER

Birr Castle Observatory, December 23, 1884

THE FORMATION OF THE SOLAR SYSTEM[1]

THE aspect of the heavens, the appearance of the planets, do not give us the least idea of the solar system. In order to understand it well, we must in imagination quit our world altogether, and remove ourselves to a distance, so as to embrace in one glance the little system of which so ordinary a star as our sun occupies the centre.

Around the sun there move eight primary planets at very unequal distances. Of these planets six have satellites; that is to say, they in their turn are centres of little systems reproducing the solar system in miniature. Thus the Earth has a satellite, the moon; Mars has two, Jupiter four, Saturn eight, Uranus four, and Neptune, the most distant, has one. A striking thing in this system, that which makes it unique, is that the sun turns on its own axis from right to left, and all the planets without exception revolve around it in the same direction, almost in the same plane, that of the rotation of the sun, and describe orbits very nearly circular.

Would not one say that a vast gyratory movement animates all these bodies, and that the secondary systems of the Earth, Mars, Jupiter, &c., are little whirlpools moving in the primary one? Such was the idea of Descartes. If the solar system does not actually constitute a whirlpool, it was originally formed by a movement of this nature in the nebula which gave it birth.

The sky exhibits here and there a large number of gigantic masses of extremely rarefied matter, like the mists of chaos, without shape, having undergone only that degree of condensation necessary to create a feeble light. We require usually a powerful telescope to distinguish them, and then we can see them by thousands in the heavens; these are *nebulæ*.

When you visit an observatory under the escort of an astronomer whom you know, tell him several days beforehand that what you wish is not to gaze at the moon, or the planets and their satellites, or the fixed stars, double

[1] Translation of an article by M. Faye in a recent number of *L'Astronomie*.

or treble, white or coloured, but only to examine the nebulæ of various degrees of condensation. Your wishes being thus indicated, the astronomer will point out to you the most characteristic objects, he will calculate their exact positions, will prepare his most powerful telescope, and then you will be able to make an interesting journey into space.

The nebula of Orion has not a clearly defined form: one region more brilliant than the rest can be distinguished, where the condensation of the chaotic matter is rather far advanced. In all other parts the light is feeble, and one can detect long streamers of matter of which it is impossible to predict the action.

The nebula of Andromeda is one of the most remarkable objects in the heavens. It has an almost geometrical form, and in the centre it exhibits a most distinct condensation.

The nebula of Leo presents nebulous rings in course of formation.

Finally, the curious double nebulæ of Virgo, Aquarius, &c., are evidently very near their ultimate transformation into stars.

It would be easy to multiply the intermediate stages, and to show, for example, some nebulous stars presenting the penultimate phase of this series of transformations, which commences with a feebly luminous mist without shape, and finally arrives at one or many suns variously connected. Needless to say, we are not present at these transformations, but we are like the botanist who in the forest studies the trees in their different degrees of development. Thus the creation of the universe is carried on, so to speak, under our eyes. In the beginning nebulæ separated out from a universal chaos; in the end, incandescent stars, or other globes so small that we cannot see them, because their formation has produced so little heat that their light is already extinct.

Let us imagine that, owing to some cause of which we shall presently speak, the spirals of a whirling nebula are transformed into nebulous concentric rings, governed by a common movement of rotation. In reality there exist in the heavens objects of this description: for example, the annular nebula in Lyra.

If such as these are rare, it is because they usually do not possess great stability. It is only a transitional form. In reality, in virtue of the differences of linear speed which predominate there, and because of the mutual attraction of their parts, the least cause will lead to eddyings, which, being obliged to follow somewhat the same road with rather different speed, reunite and are lost in a single nebulous mass, where, little by little, all the material of the rings will be absorbed. This nebulous mass, excited by a rotation in the same direction as that of the ring, will in its turn give birth to a planet surrounded by satellites revolving in the same direction and in the same plane.

We have a series of nebulous rings, some of which show the eddying condensation which ends in a mass of planets. At the same time the enormous quantity of material which in the midst of the original nebulæ was not used up in the rings, has little by little reunited in the middle, very slowly at first, but afterwards very quickly, giving rise to a central globe, a Sun, turning on its own axis in the same direction and in the same plane as the planets.

We thus see how a slow whirling movement, more or less indistinct, would be able to be governed so far as to give rise to these circular rings, all of them concentric and situated in the same plane.

It is necessary and sufficient for this theory that the solar nebula has been, in the first instance, spherical and homogeneous. In such a mass of matter the internal gravity resulting from the attraction of all the molecules varies in a direct ratio with the distance from the centre. The particles or the small bodies which move in such a medium, where the rarity is inconceivable, necessarily describe ellipses or circles round the centre *in the same time*, whatever may be their distance from that centre. Thenceforth the existence of rings rotating in one piece, with the same movement, is quite compatible with this condition of gravity, and if a whirling motion has pre-existed, some of these spirals, which are not so very different from circles, will have little by little become transformed into the rings previously described, owing to the small amount of resistance at the centre.

Let us take a step further. In virtue of the force of attraction these rings tend generally to break up and to form a nebulous spherical mass, which in the end contains all the material of the ring. Now these secondary nebulæ must necessarily be endowed with the same direction of rotation as that of the rings. Phenomena exactly like those of the primary nebula will then take place; that is to say, they will resolve themselves into concentric rings, then into a central globe. In their turn, the rings will be condensed into other very small balls—satellites revolving round each planet, always in the same direction, whilst the planet will turn on its own axis exactly in the direction and in the plane of these secondary rings.

It is thus that these things have come about. By a lucky chance some rings of the little secondary system of Saturn have escaped destruction, and have not been formed into satellites. I attribute their existence to the extreme thinness of these rings and to their rapid rotation.

We should now have finished the explanation of the solar system if this system did not offer a striking peculiarity, apparently in complete contradiction with what has preceded. Of the eight large planets revolving round the sun six have satellites, and thus form secondary worlds, exact representations of the solar world which includes them. After what I have said, all the rotations and revolutions ought to be in the same direction, and, what is more, in the "direct" direction. Now in the secondary worlds of the two planets furthest off—those of Uranus and Neptune—the rotations and revolutions of the satellites are in the opposite direction, that is to say, *retrograde*.

Must we believe that the theory that I have put before you is false? It is not false, but it is incomplete. And here we come to one of the most interesting points in the history of science. Newton and Laplace believed that all the rotations, all the revolutions must be in the same direction. Laplace went further, and applied to this question the theory of probabilities. In working on the planets and satellites as known in his day, his analysis showed that, if a new planet or satellite was discovered, the chances were tens of thousands to one that the revolution of this or that satellite, or the rotation of this or that planet, would be direct, like all the others, and he added that this probability is much greater than that of historical events which we accept with the utmost confidence. The study of the satellites of Uranus, and the discovery of the system of Neptune, however, has at once destroyed this probability, and the celebrated cosmogony of Laplace. This in fact by an ingenious process derives all the planets from the sun, but it can only give to the planets and satellites relations and revolutions in the same direction from one end of the solar system to the other, whilst in fact they are direct in the first half and retrograde in the second.

Let us actually complete our theory. In the primitive nebula, homogeneous and spherical, where the presence of rings revolving round the centre ought not to alter anything in the law of internal gravity, we have seen that this gravity varies in a direct ratio with distance from the centre. But, later, the sun was formed by the reunion of all the matter not wanted for these rings; this has produced an empty space around it. Therefore the law of gravitation in the interior of the system thus modified became quite different. Under the action of the preponderating mass of the sun (that of the rings was not

the 700th part of it) the internal gravity has varied, not in the direct ratio of the distance, but in the inverse ratio of the square of the distance from the centre, and that is the state of things to-day.

In this last case the method of rotation of a ring of diffused matter entirely changes. Let us hasten to say that this alteration does not hinder the ring from existing. Saturn is the proof of it.

But whilst, according to the law of gravity first in operation, the linear velocity of revolution in these rings increased with the distance; according to the second, this velocity on the contrary decreased in the ratio of the square root of this distance.

In the first case, when the ring will have degenerated into a secondary system, that is to say, into a nebula with exterior rings, and finally into a planet with its satellites, the rotation of the planet and the revolution of the satellites will be in the same direction as the movement of the original ring, that is to say, the motion will be "direct." In the second case the secondary system thus formed will be retrograde.[1]

What are we to conclude from this? It is evident that the planets from Mercury to Saturn, included in the central region, were formed according to the first law, when the sun did not yet exist or had not acquired a preponderating mass; and that the planets included in the exterior region, which was by far the larger, were formed when the sun had already come into existence.

If then it should be discovered that Venus had a satellite, its motion would be direct. If a planet were discovered outside Neptune, its rotation and that of its satellites would be retrograde. Here we have at last arrived at a conclusion of the greatest interest: the earth is much older than the sun. If it were otherwise—if, as Laplace would have said, its formation had been long after that of the sun—all would have been changed in the aspect of the skies: the stars would rise in the west and set in the east; the moon would have a retrograde motion, like the satellites of Uranus and Neptune. Let us add that at that time it was further from the centre than it is now; for when the matter which was outside the terrestrial orbit had passed over it to be reunited in the interior to orm the sun, as the attraction of the latter gradually preponderated, the revolution of all the planets within the orbit of Uranus was accelerated. These planets approached the sun at the same time that their satellites receded from them.

Finally, the actual state was attained, with the stability which characterises it, when the mass of the sun, having become enormous, could attract nothing more from the original nebulous matter, and had at last created around itself an empty space.

The universe has grown out of chaos, that is to say, out of a mass of matter excessively rare, without shape, occupying a vast space and moving in various directions, in virtue of which this chaotic matter was divided into separate masses. It is by the progressive condensation of these masses of chaotic matter towards certain centres of attraction that the innumerable stars have been formed. Their incandescence comes from the heat developed during the act of their formation. The amount of their heat is limited; they will end by being extinguished.

Amongst all the systems, which are infinitely varied, which have grown out of the condensation of this primary chaos, the solar system may be regarded as a very special case. The primary nebula which gave birth to it was spherical and homogeneous. In separating itself from other portions it had carried with it traces of a slow whirling movement. These motions were soon regulated, thanks to that particular law of internal gravitation resulting from its shape and its homogeneousness. Nebulous rings were thus formed in the same plane long before the appearance of a central condensation. They gave birth to nebulous masses also moving in this plane, in the same direction and in circular orbits, around their common centre.

The secondary systems formed in the same way into these partial nebulæ can be definitely separated into two categories: those which preceded the formation of the sun, revolving on their own axes in "direct" directions; whilst the secondary systems, the furthest off, formed after the sun, revolve in a retrograde direction. These strange phenomena which are presented by our solar system, are doubtless, by a rare exception in the universe, only the natural consequences of the initial conditions and of the laws of mechanics.

[1] Laplace believed that in the nebulous rings derived from the sun (according to his hypothesis)—rings which will have belonged to the second case as they would be exterior to the sun—the friction of different concentric layers would have had the same effect as what occurs in the atmosphere of a planet, which ends in moving altogether with the central globe. In this way the ring will have taken on the movement of the first form, that is to say a rotation; its outer marginal layers will have had a greater linear speed than that of the layers nearer the centre, and its condensation will have given place to satellites with direct motion It is easy to show that this manner of looking is not altogether exact (in proof of this we can point to the rings of Saturn). The layers of an atmosphere press on one another; further, the external layers only resist by their inertia to the communication of the rotatory movement which tends to establish itself between the central globe and the extreme layers of its atmosphere. But, in a nebulous ring, the concentric layers do not press one on the other as in an atmosphere, for each one moves in virtue of its own speed at its distance from the sun. Further, the retardation of the layers situated near the extreme edge as compared with the internal layers is not due to their inertia, but to the laws of their motion. If then the solar system has been created in accordance with the hypothesis of our great geometrician, all the planets would have revolved round the sun in the direct direction, but their rotations and their satellites would be retrograde.

BERZELIUS AND WÖHLER

THE "Jugenderinnerungen eines Chemikers," which the late Prof. Wöhler contributed to the *Journal* of the German Chemical Society in 1875, contains a delightful sketch of the personal relations in which the great German chemist stood to his illustrious master; and Dr. Hofmann's account of Wöhler's life and works, published in the same journal for 1882, serves to fill in the details of the picture. The story of Wöhler's visit to Stockholm, of his intercourse with Berzelius, and of the influence which it exerted on the development of his scientific life. are now well known to chemists.

All the papers left by Berzelius are in the possession of the Swedish Academy of Sciences at Stockholm, and among them are the letters which he received from Wöhler. Some time before his death Wöhler presented his letters from Berzelius to the Academy with the injunction that they were not to be published before the close of the present century. Some extracts from the letters of Wöhler, on the publication of which no restriction was made, have recently been given to the world by Dr. Edv. Hjelt of Helsingfors,[1] from which we may gather some notion of the wealth of material which will be at the disposal of him whose lot it is to write the personal history of the chemistry of this century.

Wöhler's letters to Berzelius extend from 1823 to 1846, and are 230 in number. In all probability the correspondence was continued up to the time of Berzelius's death in 1848, but the letters of the last two years are not contained in the collection. The greater portion of the letters from Wöhler consist of accounts of his investigations, of discussions of scientific questions, of critical opinions on new works and new theories, and of *memorabilia* of the chemists of the time. Many of the letters have reference to the translation of Berzelius's "Jahresberichten" and his large "Manual of Chemistry" into German. Now and again we have a gossiping letter, rich in a quiet humour, and occasionally illustrated by quaint characteristic sketches. First in order of time comes Wöhler's application for a place in Berzelius's laboratory, dated July 17, 1823, and next is his grateful acknowledg-

[1] "Bruchstücke aus den Briefen F. Wöhlers an J. J. Berzelius." Herausgegeben von Dr. Edv Hjelt. (Berlin: Robert Oppenheim, 1884.)

ment of Berzelius's prompt and cordial acquiescence in his wish :—

"Wie sehr freue ich mich auf diesen Winter," he writes, "wo ich mich einmal so ganz *con amore* der Chemie ergeben kann, ohne die Zeit in andere, mehr oder weniger fremdartige, nicht so ansprechende Studien theilen zu müssen."

Wöhler remained about a year in Stockholm ; he was wont to speak of his stay with Berzelius as "eine nicht zu berechnende Wohlthat." As to Berzelius, no one of his pupils lay nearer to his heart than Wöhler.

In the selection of his letters it is obvious that Dr. Hjelt has been loyally mindful of the condition imposed by Wöhler. Doubtless much of the correspondence had reference to letters of Berzelius, and therefore to matters which the world can only know of in the twentieth century. The letters which we are permitted to see have, however, a great interest from the light they shed on the writer's character, and from the accounts they give of the origin of those fruitful discoveries which have made the names of Liebig and Wöhler inseparable. How that partnership originated need not be told again. It seems, however, that in more than one letter Berzelius had expressed his conviction that Wöhler's share in the work was but imperfectly recognised. That Wöhler was, in fact, the mainspring of much of their labour is now known, but he himself writes, "What matters it, however, when the business in hand profits thereby, and such is assuredly the case. We two, Liebig and I, have dissimilar kinds of talent ; each, when in concert, strengthens the other. No one recognises this more fully than Liebig himself, and no one does me greater justice for my share of our common work than he."

In the following letter we get a glimpse of Liebig's mode of work :—

"The days which I spend with Liebig slip by like hours, and I count them as among my happiest. His apparatus for organic work seems to me most excellent, and he is a master, of almost pedantic exactitude, of organic analysis. But in all that relates to inorganic analysis, as, for example, filtration, use of lamps, &c., one sees throughout the imperfect French methods. He uses neither a filter-stand, nor good filters, nor usually a lamp. . . ."

Liebig's earnestness, and restless energy, and fiery impulsiveness, brought him unfortunately into frequent conflict with his contemporaries. It was almost inevitable that he and Berzelius should sooner or later come into collision. Nothing in the letters is more charming than the manner in which Wöhler sought to maintain peace between his friends, constantly seeking to excuse the one to the other. He writes of Liebig to Berzelius :—

"He is thoroughly upright, honourable, and generous, but passionate and inconsiderate."

At another time he wrote :—"He who does not know him intimately would hardly realise that at bottom he is one of the most good-natured and best fellows in the world."

It is somewhat remarkable that Wöhler, although trained in a school of which analysis was made the predominant characteristic, should have failed to discover any new elementary body, even whilst constantly occupied with the examination of rare minerals. We all remember the story of Vanadis and the "Schalk" Wöhler, who failed to woo her with proper assiduity. It now appears that the element thorium also slipped through his fingers unperceived. "Also," he wrote, "eine analoge Geschichte mit dem Gotte Thor, wie mit dem Göttin Vanadis." Wöhler's triumphs were won in organic chemistry. "The organic chemistry of to-day," he wrote in 1835, "is enough to make one quite dazed. It is like the primeval forest of the tropics, full of the most curious things ; an immense thicket without exit and without end."

One of the most historically interesting letters of the series is that in which he communicates to Berzelius his memorable discovery of the synthesis of urea—"ohne dazu Nieren oder überhaupt ein Thier, sei es Mensch oder Hund, nöthig zu haben." It now appears that the transformation of ammonium cyanate into a body which gave no reactions for either cyanic acid or ammonia was observed by Wöhler whilst in Stockholm, but the significance of the change escaped him for the time. How, almost accidentally, he returned to the subject, and how by three or four decisive experiments he establishes the nature of the new body, is shown in the letter. Berzelius had not then invented the word "isomerism." For a time, indeed, his conservatism rebelled against the conception. Wöhler's words in reference to urea—"This is therefore an incontestable example that two absolutely dissimilar bodies can contain the same proportion of the same elements, and that it is merely a difference in the mode of combination which brings about the dissimilarity in their properties"—must have paved the way for Berzelius's conversion. How strange, too, the following sentence must have sounded in 1828 ! "May not this artificial formation of urea be regarded as an example of the production of an organic substance from inorganic materials ?"

The witty and sarcastic letter which appeared in the *Annalen* for 1840, in which "S. C. H. Windler, aus Paris," sought to ridicule the substitution theory of Dumas, was at the time generally ascribed to Liebig, but we know now that it was written by Wöhler for the amusement of Liebig, "ohne dass ich aber im Entferntesten daran dachte dass er so toll sein wurde ihn in den Annalen Abdrucken zu lassen."

Wöhler not unfrequently amused himself and his friends with *allotria* of this kind. The well-known flash which attends the crystallisation of plate sulphate of potash was on one occasion thus explained :—"Die Lichtfunken bei krystallisirenden Salzen hängen mit einer gleichzeitig im Krystall vor sich gehenden isomerischen Umsetzung der Bestandtheile zusammen, z. B. ein krystallisirtes Schwefelsaures Kali könnte eigentlich unter gewissen Umständen KSO_4 or KO_3SO geworden sein. Nun aber arrangiren sich plötzlich die Atome zu $KOSO_3$ und dabei blitzt es, weil in dem einem Falle Kalium zu Kali, und in dem anderen unterschweflige Säure to Schwefelsäure verbrennt. Ich will diese Idee an Kastner verschenken."

Berzelius died on August 7, 1848, after a long illness. Almost his last words had reference to Wöhler. Wöhler always spoke of their friendship as one of the brightest memories of his life, and we are told that even to the last the eyes of the old man would glisten when the name of Berzelius crossed his lips.

T. E. THORPE

AMERICAN STORM WARNINGS

THE Meteorological Office, through the co-operation of the Chief Signal Officer of the United States War Department, has commenced to issue notices of the current Atlantic weather, and it so happens at the very commencement of the system that the frequent occurrence of storms in the vicinity of the British Islands, as well as out in the open Atlantic, has afforded a favourable opportunity for testing the value of this extension of our weather knowledge. As a specimen showing the nature of the information, we append a copy of the notice issued on December 19 :—

"The Chief Signal Officer at Washington, U.S., reports that, at 4 a.m. on the 16th inst., in lat. 42° N., long. 60° W., with the barometer at 29·4 inches, there was a fresh gale from south, veering to west."

A subsequent notice was issued, showing that the same storm was met with eight hours later, and had advanced rapidly to the east-north-eastwards. It appears highly probable that the disturbance in question was the same

as that which passed swiftly across our islands during the night of the 19th to 20th, and had its centre off Yarmouth at 8 a.m. on the 20th, having travelled about 2600 miles in four days and four hours, or at the rate of twenty-six miles an hour. This rate is somewhat high for an average extending over so long a period, but it is in accordance with former experience for an isolated storm-centre, and is fully supported by the high rate of progress the storm had when traversing England. The barometrical gradients in the rear of this storm were very steep, and the difference of pressure was accompanied by a heavy gale on the 20th over the whole of the southern portion of our islands.

We are glad to see that the Meteorological Council are taking steps to ascertain the atmospheric changes which are going on over the Atlantic, since the weather of that ocean has such an important bearing upon that of the British Islands. It is now no longer a matter of speculation as to where the weather comes from which strikes our coasts, but the synchronous charts which have been prepared by the Meteorological Office, both under Admiral FitzRoy and the subsequent governing body, as well as by Leverrier, Hoffmeyer, Neumayer, and the Signal Service of the United States, amply prove that in the north temperate zone of the Atlantic, at least, there is a regular movement of the weather-systems from west to east, or, more strictly, from some point between west and south-west towards east and north-east. These weather-systems not only embrace storm areas, but, to a very large extent, all the ordinary weather changes. It is our intention here, however, to limit our remarks to the question of storms and unsettled weather, as not only being of primary importance, but the conditions with such weather will, although of a more pronounced type, illustrate in a very great measure almost all other meteorological changes.

Probably the enterprising proprietors of the *New York Herald* have done more of late years than all other authorities put together to popularise the fact that our weather changes traverse the Atlantic, but the notion, if nothing more, of the easterly translation was in existence 180 years ago, for Daniel De Foe, in his discussion of the great storm of 1703, inclines to the opinion that it came from America, since, as he says, "they felt upon that coast an unusual tempest a few days before the fatal 27th of November."

The United States Signal Service has for several years past published monthly track charts of all storm-centres in the North Atlantic, and the most cursory examination of these is sufficient to prove that very valuable information might be transmitted to Europe from America with respect to the weather experienced by trans-Atlantic steamers on their outward passage. Prof. Loomis, who has devoted considerable attention to the tracks of Atlantic storms, has calculated the average velocity of storm-centres in the Atlantic Ocean to be fourteen miles an hour, and has shown the rate of progress to be less over the sea than over either America or Europe. Some other authorities have given rather a higher rate of progress than Prof. Loomis, but when a large number of instances is taken it will not be found that the average rate exceeds twenty miles an hour, and probably this rate is the safest that our present knowledge of the subject will allow. The charts of the United States Signal Service for 1879, which exhibit the tracks of ninety-two distinct storm-centres in the Atlantic, show the average rate of progress of all these storms to be eighteen miles an hour. From this it will be seen that, with the speed now attained by many of our principal steam-vessels engaged in the trans-Atlantic trade, if a storm is met anywhere to the westward of the mid-Atlantic, a vessel can, on arrival at a port in the United States, transmit timely notice to Europe that a storm has been experienced, and such notice will serve as a caution to our home authorities to be on the alert for any evidence of our outlying stations indicating the approach of the storm until its subsequent arrival, or until ultimate proof is obtained that it will not strike our shores. The fact that a storm is blowing out in the Atlantic will also probably be valued by commanders of vessels who are leaving port bound westwards.

The Atlantic gales differ so materially from each other in their character that any information which will convey the nature of an impending storm, either to vessels outward bound or to those engaged on our coasts, will be of the highest importance. It sometimes happens that the whole of the northern part of the Atlantic is taken up with one vast disturbance, the wind blowing with the force of a gale over an area having a diameter of upwards of 1500 miles, and occasionally extending from the coast of America to Europe. On the other hand, several disturbances may exist at one time between the two continents, and in this case a vessel is no sooner out of one storm than she enters the margin of another, and these conditions may last throughout her passage. This will be readily seen from the synchronous weather work already referred to; and, if further proof is wanted, it is to be found in the frequency with which storm-centres pass either over our islands or in their immediate vicinity, and in sufficient proximity to influence our winds and weather, if not near enough to give gale force to the wind.

The British Islands are probably less favourably situated for the successful issuing of storm warnings to our own coasts than any other country, since they are in the direct path of the Atlantic storms, and they have not the advantage of any stations within reasonable distance to the westward beyond their limits by which they may be warned, so that it often happens that a storm is almost upon us before its approach is foreseen. An attempt was made some years ago to moor a vessel at the entrance to the English Channel and to connect it by a telegraph cable with our coast, but the attempt was a failure, and experience has shown that the step now taken by the Meteorological Office to obtain Atlantic weather information is the only one which promises success.

THE ACTINIÆ[1]

THIS is a work which contains far more than it promises. Though commenced with the intention of describing only the Actinians (sea-anemones) of the Bay of Naples, it has extended until it includes all the species known; and although at first sight it seems nothing more than an ordinary systematist's manual—a dry dictionary for the specialist—it turns out on closer examination to have a clearly-marked individuality of its own. In its preface the author remarks, with a tinge of dry humour which here and there ripples the clear precision of his style, that in these days of papers full of histological detail, or rich with plates of caryolitic figures, embryological sections, or genealogical trees, his big book, apparently so purely systematic, may at first excite among his scientific brethren a smile of compassion, if not indeed a word of contempt. Far, however, from renouncing his intellectual birthright of wider scientific aims, he claims with justifiable pride to have produced (and at a self-denying outlay of time and toil not excelled by that of any histological investigation) no mere arid catalogue of genera and species, but a summary of the whole past of actinology, and a new starting-point for the future. He promises, too, a second volume, in which the anatomy, histology, and development, the physiology, distribution, and phylogeny, will be discussed, and no doubt as exhaustively.

The bibliography alone is well worth notice, for its scholarly precision and thoroughness furnish a royal road

[1] "Fauna und Flora des Golfes von Neapel. Le Attinie." Monografia del Dr. Angelo Andres. Vol I. Bibliografia, Introduzione, e Specigrafia. (Leipzig: Wilhelm Engelmann, 1884.)

to their next investigator, for whose benefit also the most elaborate system of general and special indexes is provided. The history of actinological progress is critically exposed, and even the humblest species-maker scrupulously receives his tiny share of immortality, while the veriest trifles of etymology, popular nomenclature, or culinary use, are not forgotten.

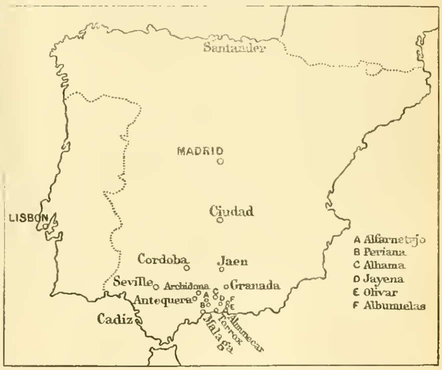
Far more important, however, is the clear schematic account of actinian anatomy, with a recast morphological nomenclature, and thereupon follows the plan of the monograph, where our author briefly outlines the general view of biology and of the relations of its sub-sciences which dominate the work. This agrees largely with that usually adopted in this country (cf. Prof. Huxley's article, "Biology," in the "Encyclopædia Britannica"), but differs from it in some important respects, notably in the separation of taxonomy into *Specigrafia* and *Sistematica*. Next follows a keen re-discussion of the conception of *species*, and the limits of *genus* and *variety*. The last he proposes admitting as a rule, and then by giving variety an analytic and genus a synthetic aim, and making both changeable as systematists find expedient, he hopes to keep the conception of species near a more constant average. After some useful remarks on nomenclature, the systematic detail is entered upon, and the known species (520 or more), with their endless varieties, described with exquisite minuteness. Numerous diagrams aid the work of identification, and the volume concludes with thirteen magnificent plates, which reflect the greatest credit alike upon the author's pencil and the care of his lithographers, Messrs. Werner and Winter. The classification differs so much from existing ones as almost to be new. Two new families, *Edwardsinæ* and *Stichodactylinæ*, are created; the *Ilyanthidæ* are almost abolished, the *Minyadinæ* wholly so.

If space permitted, one or two trifling criticisms might be offered, if only to accent the general praise; yet it is better to welcome the book unreservedly as a new sign of the scientific *renaissance* of Italy, and its author as henceforth one of its leaders, who has learned philosophic breadth from the "Origin of Species" without losing the detailed accuracy of the "Monograph of the Cirripedia."

A word finally as to the splendid series of monographs to which this belongs, and which, together with the *Challenger* volumes, mark an epoch in biology. Is it not lamentable that such works—which, if not yet indeed. in time-honoured phrase, "books which no gentleman's library should be without," are certainly needed in every public library, and which even no local natural history society can afford to be without—should be limited to an impression of, after all, only a few hundred copies by the apathy or ignorance of the scientific public? P. G.

THE EARTHQUAKE IN SPAIN

AN earthquake of wide extent and unusual violence took place on Christmas night in the southern provinces of Spain and in the neighbourhood of Madrid. The accompanying map may give some idea of its extent. As many of the towns and villages of Granada, Malaga, and Andalusia are unconnected with the capital by telegraph, the full extent of the damage is not yet known, but enough information has been received to mark the present as among the most destructive earthquakes of recent years. No precise observations as to time or direction have yet reached this country; and the officials at the Madrid Meteorological Observatory are reported to have made no observations at all, for there were no funds to purchase instruments for such a purpose. Madrid itself was within the disturbed area, but it was probably on its extreme north edge, for the effects of the shocks there were slight, and were confined to the rattling of windows, the ringing of bells, and the like. But in the three southern provinces the destruction was great and widespread, involving in many cases considerable loss of life. There were several shocks, overthrowing whole villages and burying the inhabitants in the ruins. In Arenas del Rey 40 persons were killed, in Albuequeros 150, in Olivar 10, and in Cajar 12, and similar numbers in many of the towns and villages of the three provinces. The number of killed on the whole is put down in Madrid, from the reports of the local officials, at more than 1000. Even in large cities such as Granada, Malaga, Jaen, and Seville great damage was done, and much excitement prevailed. The inhabitants encamped in the open air through fear of fresh shocks. At Granada the front of the Cathedral was seriously injured, but the Alhambra was untouched. There is much discrepancy in the reports as to the duration of the earthquake: some village authorities have reported ten distinct shocks, while in other cases it is stated that there were seismic disturbances intermittently on the 26th, 27th, and 28th, the three days succeeding the great earthquake. This is especially reported from Jaen, where there should be ample means of corroborating the statement. At Cadiz a panic occured in the theatre; in Malaga the Cervantes Theatre was much injured. It is noticeable that a sharp fall of the barometer was noticed all over the south of



Spain in the afternoon before the earthquake, and that there have since been frequent fluctuations. There is some doubt whether the number of persons who have lost their lives will not far exceed a thousand, inasmuch as the reports, as they grow more detailed, instead of diminishing, largely increase the original estimates. At Periana, in Malaga, a landslip on a mountain in the neighbourhood destroyed a church and 750 houses, from the ruins of which the dead and injured were being taken: similarly at Loja half the houses were overwhelmed. The town of Alhama in Andalusia is reported to have been completely destroyed, with 300 persons. A report is published with regard to Albunuelas, stating that 900 persons are believed to have been killed under the houses thrown down by the earthquake. This would be about one-half the population of the town. At Antequera the shocks have left three churches in a dangerous condition, and the inhabitants are camping in the fields; the Cathedral at Seville, especially the Giralda tower, is much damaged; at Granada the richer classes are living in their carriages, which are stationed on the public promenade; the others camp out in the squares and open spaces; at Cordova the inabitants are flying from the town. The loss in the town of Malaga is put down at 100,000*l.*, 227 buildings being injured. It would appear that five distinct shocks took place in this town on Christmas night, and three on the following morning. Five shocks on Friday and

Saturday are reported from Antequera, and nine from Archidona. That the disturbance has not yet ceased is shown by the report from Torrox that the shocks were renewed there on the morning of the 29th, shaking the foundation of the Town Hall, and causing cracks in the walls of other houses; while other violent shocks are reported from Malaga and Granada on the evening of the 30th, one at 7 and the other at 10 o'clock. In connection with these after-shocks, a report from Tarvis, in Carinthia, states that an earthquake was felt there on Sunday, which by the oscillation it caused cracked the walls of many houses. The Spanish earthquake was not felt in the north and north-western provinces. No precise information as to the times of the shocks at the various places has been received. At Xerez and Cadiz, according to one account, the first smart shocks occurred shortly before 9 o'clock, and other slighter shocks about midnight and 4 o'clock the next morning. At Ciudad Real no damage appears to have been done, beyond the alarm to the inhabitants, who passed the night in the open, fearing a recurrence of the shocks. At Velez Malaga and Malaga proper several shocks injured the theatre and the churches, the falling masonry killing several persons. The clocks are stated to have stopped in various parts of Andalusia at from ten to seven minutes before nine, which may therefore be taken as the time of the first shock.

We have received the following correspondence on the subject of the earthquake:—

Yesterday, 25th, at 8h. 53m. p.m., slight earthquake in Madrid: two distinct shocks in 3 to 5 seconds; house bells set ringing and lamps and other suspended objects swinging; the oscillations were almost due east and west, which gives north and south as the direction (rough) of seismic disturbance. This was evidently stronger in some parts of the town than others, as out here it produced no effect outside, whereas according to this morning's paper much alarm was produced in some streets by people rushing out of their houses. But earthquakes are very uncommon in Madrid, and this accounts sufficiently for the scare. There really was no particular cause for alarm. Official telegrams report shocks felt at about the same time in Cadiz, Malaga, Granada, and Cordova.

F. Gillman

Quintana, 26, Madrid, December 26, 1884

I have reason to believe that this commotion extended to England. On the night of December 25 I left my family quietly seated round the fire at 10 o'clock. Being in bed myself at about 10.20, I perceptibly felt a shock of earthquake such as I have often experienced in the vicinity of Naples, and I said to my wife, who came up shortly afterwards, "I have felt a distant shock of earthquake. if there is nothing moving downstairs," which from the distance of the offices there certainly was not. The motion, we learn, was from south to north, and the usual rate of movement corresponds well with the time of the occurrence—say 6 minutes to 9 at Madrid.

The Rookery, Ramsbury, Wilts — Alfred Batson

THE HABITS OF THE LIMPET

The following observations upon the habits of the common limpet (*Patella vulgata*) were made during last July at the Scottish Marine Station, Granton, Edinburgh. I am much indebted to Mr. John Murray, the manager of the Station, for kindly placing its resources at my disposal, and also to Mr. J. T. Cunningham, B.A., the director, for much kind advice and assistance.

The *Ark* is moored in the centre of a flooded quarry, upon whose faces large numbers of limpets are to be found. As parts of these faces are almost or quite vertical, it was easy to take a boat round and make observations during all states of the tide. The few that were made bear on the feeding and locality-sense of the form in question.

By far the larger number of limpets "roost" upon rocks whose only covering consists of minute green algæ and nullipores, together with numerous acorn barnacles. These last are seen to be of very unequal degrees of "cleanness," some being covered with vegetable growth, others quite white and bare. Those immediately surrounding a limpet or group of limpets are invariably free from algæ. As might have been anticipated, Patella is the cause of this freedom. At low tide anyone on the look-out can hear a quick, regular, rasping sound in all directions, and see numerous limpets slowly crawling about. Scrutiny of any particular individual shows that the rasping noise is caused by strokes of the radula, which speedily scrapes away the incrusting algæ. Whilst "on the feed" a limpet moves steadily on, pretty much in a straight line, and continually sweeps its elongated snout from side to side, feeling out probably suitable patches whereon to graze. When such a one is discovered, it is gradually licked quite clean. If the patch happens to be the surface of a moderate-sized barnacle, the circular lip is completely spread over it, almost tempting one to believe that the crustacean is about to be "sawn out." Such, however, is not the case, "house-cleaning" being the sole end in view. Indeed, limpets are often serviceable to one another by thus clearing away esculents growing upon their shells. To secure a dinner, a good deal of licking is requisite, and perhaps this habit may help to account for the inordinate length of the tongue-ribbon. Certainly it must be used up at a very great rate.

But this is not the only, though I believe the chief, way in which the limpet feeds. Those individuals which live near large sea-weeds, such as Fucus, feed extensively upon them, as their gnawed condition testifies. I can speak confidently in this matter, having caught more than one limpet in the act. The operation was as follows:—The edge of a thick flat part of the thallus was seized by the lip (as a traveller might commence on a colossal sandwich), and being, I suppose, held firmly by the upper jaw, a semicircular "bite" was gradually excavated by successive scrapes of the radula, the edges of the bite being bevelled on the under side. So far as my observations extended, limpets do not feed when covered by water, but always settle down firmly before the rising tide reaches them. The intervals between which any particular limpet feeds seem to be very irregular; but, as a rule, the largest limpets are apparently least fond of long fasts.

In regard to the second point, the locality-sense, great doubt seems to exist in the minds of naturalists as to whether limpets go back to the same place to roost. I believe the question was answered in the affirmative long since by a Mr. King, but, as far as is known to me, he did not publish any details of his observations, and this is my excuse for giving an outline of mine. Following a suggestion of Mr. Murray, I marked a number of limpets with white paint, and made corresponding marks near their "scars" with a view to "keeping my eye on them." As Dr. S. P. Woodward remarks, it seems probable from an *a priori* point of view, that limpets have a settled home, for they occupy scars, often sunk to a considerable depth, which *exactly* correspond to the outline of the shell. My observations, made on numerous specimens of various sizes, completely confirm Mr. King's opinion, and the method of marking rendered cases of "mistaken identity" quite out of the question. The greatest distance from its scar at which I noticed a marked limpet to be, was about three feet; yet this distance, though extremely rough, and covered with barnacles, was re-traversed without difficulty. The excursions from the roosting-places were made in any direction where food offered; so there were nothing like beaten tracks formed. But a limpet always returns home before the rising tide reaches it, and invariably

roosts with its snout pointing in the same direction. As might be expected, this direction is only constant for individuals. As the shape of the scar corresponds exactly with the shape of the shell, comfort, of course, could only be gained and a firm hold effected by limpets roosting permanently in the same direction on their scars.

The question now arises, What sense is employed by the limpet in finding its way back to its scar? The appreciation of locality displayed is certainly, for so simply-organised an animal, very keen. The sense of sight is evidently out of court, for an eye like the limpet's, consisting of no more than a sensitive cup, could do little if any more than distinguish between light of different degrees of intensity. The tentacles seemed at first sight to be extremely likely organs to use for the purpose, and to decide this I excised those of two marked individuals which were off their scars. One speedily found its way back; the other seemed confused by the operation for several days, but after that time was found on its scar. This shows a remarkable power of memory, unless the scar was found by accident, which is possible, as the individual was near home when the operation was performed. But even in that case the scar must almost certainly have been *remembered*. Thus, the tentacles do not seem to be the means by which home is returned to. The sense of smell then suggested itself, and it occurred to me that one reason why limpets kept on their scars when covered by the water was to prevent the "scent" of the track traversed from being washed off. With a view to determine this the space between a wandering limpet and its scar and the scar was carefully washed again and again with sea-water. In spite of this the limpet in question readily found its way back again. Further experiments are, however, needed on this head, for any ordinary washing would be very ineffective compared with the prolonged soaking the tide would effect in the case of a limpet (like the one just mentioned) living some distance below high-water mark. Still some limpets live so near this last that they are covered but a very short time, and yet these remain on their scars during that time. Hence I think some other motive probably induces them to remain firmly fixed to their scars when under water. Of course they can hold on best when so fixed, and this suggests the most likely reason for the habit, *i.e.* to avoid being washed off the rocks by the tide. I am inclined to think that the snout plays some part in helping the limpet to get home, as this organ is extremely sensitive, and certainly plays an important part in discovering suitable food. I intend carrying on more extended observations with a view to the more complete elucidation of this puzzling question in regard to the limpet's locality-sense, but this preliminary notice may possibly be of some interest. J. R. DAVIS

University College of Wales, Aberystwith

THE MEDITERRANEAN FAUNA[1]

VERY welcome to all zoologists, especially to those living in Europe, will be the first part of what promises to be a most useful work on the animals known to inhabit the Mediterranean Sea For more than twenty-five years Prof. J. Victor Carus tells us he has been collecting the materials for such a volume, and now that he has to be congratulated on the appearance of so much of it, we trust it may not be long ere we shall be enabled to announce that it is complete. The first part gives a list of the Cœlenterates, Echinoderms, and Worms. The next will treat of the Arthropods, Mollusks, and Vertebrates. The author on mature deliberation resolved to omit from the enumeration the Protozoa and Sponges, not seeing his way to give of these satisfactory detailed diagnoses, and also because, while Haeckel and others have done a good deal towards increasing our knowledge of the Mediterranean Protozoa, and Oscar Schmidt and others have done the same with the Sponges, yet the groups have not been rigidly systematised in the same way, for example, as the Cœlenterates.

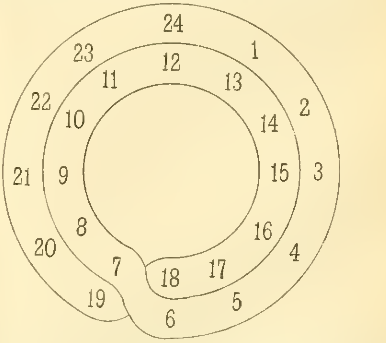
In the Prodomus, a diagnosis of each sub-order, family, genus, and species is given, with the synonymy of each species, its general distribution, and then its known habitats in the Mediterranean. When the species has been found only in the Mediterranean it is specially marked, the only exceptions we notice to this rule being in the case of the parasitic worms, and from the nature of their hosts they are just as likely as not to be found out of bounds. We have examined the list of the species with a good deal of attention, and have been greatly struck with the immense care that has been evidently used in its compilation. Many of the records and descriptions of these species are not to be found in monographs or special treatises on the fauna of certain well-known bays, like those of Naples, Marseilles, &c., but lie scattered over the numerous pages of our periodical literature, often difficult to be got at; indeed, in some few cases, we notice the record of the habitat is based on the authenticated examples in museums. In admitting some doubtful species on the authority of authors of good repute, Prof. Carus has acted wisely, for, should it be necessary, a stroke of a pen would suffice to reduce these to synonymic rank, while, should they be ultimately approved of, they are already in their places.

This Prodomus is dedicated to Sir Henry Wentworth Acland, K.C.B., who for these long years past has taken so much interest in zoology in connection with Christ Church, Oxford, and who well merits this tribute of respect and confidence from Prof. Carus. Those whose knowledge of zoology in Oxford only dates from the period of the New Museum, and who have no leisure for mastering the details of the past, may not be aware how much the collection of zoology and comparative anatomy owes to the labours of Victor Carus, who collected, we believe, for Sir Henry Acland during a great part of 1850, at the Scilly Islands, the series of British Invertebrates then placed in Christ Church Museum, and now Prof. Carus, having taken a larger area within his grasp, associates this Prodomus of its Fauna with our Oxford Professor, as a sign and token that he has not forgotten those earlier days.

[1] "Prodomus Faunæ Mediterraneæ, sive Descriptio Animalium maris Mediterranei incolarum quam comparata silva rerum quatenus innotuit adjectis locis et nominibus vulgaribus eorumque auctoribus in commodum Zoologorum congessit Julius Victor Carus." Pars 1. Cœlenterata, Echinodermata, et Vermes. (Stuttgart, 1884.)

OUR FUTURE CLOCKS AND WATCHES

IN connection with what we have said before on this subject we give a drawing of the new dial in use on some of the American railways where the new system is already



at work, the clocks indicating a certain number of hours plus Greenwich, according to the longitude of the section.

The intersection of the two circles of figures serves the purpose of giving day hours inside and night hours outside.

NOTES

THE Congress of the United States some time ago appointed a joint committee of senators and representatives to consider the organisation of the different bureaux of the Government. This special commission is now hearing the depositions of witnesses. The evidence of Major Powell, Director of the Geological Survey, has just been published. The principal feature of this document is the proposal to give the administration of the different bureaux to the Smithsonian Institution. It should be noted that the National Academy of Sciences passed some time back a resolution asking that a special administration should be created for the purpose. The Committee of the Academy recommended the establishment of a physical observatory to investigate the laws of solar and terrestrial radiation, and their application to meteorology, with such other investigations in exact science as the Government might assign to it; and they also recommended that the functions of the Bureau of Weights and Measures, now performed by the Coast Survey, be extended so as to include electrical measures.

THE Bureau of Navigation of the U.S. Navy Department announces that the computations and discussions of the observations and experiments for determining the velocity of light have been completed, and are being prepared for publication.

THE Fourth Circular of Information of the United States Bureau of Education reports the meeting of the Superintendents of National Education at Washington in February last, one of the largest of such meetings ever held. The principal papers read were on the subjects of Indian and Negro education. One speaker, who reported the former of these races to trust too much to memory and direct observation and too little to reasoning, nevertheless considered them worthy to be absorbed into the white population, though as an inferior element. This may be the best for the Indians, for the most hopeful view of another speaker who upheld the return of their educated youth to their old homes as a civilising power to the whole body, was that "not more than five out of thirty were given up as hopeless"! But as eminently qualified and well-paid men are required for even this result, and nature will probably protest strongly against the deterioration of a higher race by a lower one, the most satisfactory consideration seems that the Indian population is decreasing. But not so the Negro; and the inability of the Southern States to overcome the rapidly increasing mass of ignorance now cast upon them has led to the drawing up of a very cautious Act for the supply of national assistance to this necessary work during the next five years only. It is interesting to note that the Peabody Trustees are becoming quite an authority in educational matters. Another subject fully discussed, but, like the above, requiring little discussion in our country, was the advantage or disadvantage of a ten minutes recess during a three hours' school sitting; the objections to it, some of them social, would not be felt here. Out of our reach also, we fear, is the pleasanter matter of the plantation of trees as memorials of each great man or event at an annual school holiday. An interesting account given of the composition of those touching lines, "Woodman, spare that tree," concluded an eloquent paper on behalf of the practice. In an account of European technical education a very high place is awarded to the Swedes, who want nothing but qualified teachers. While one speaker urged that technical training should be the groundwork of education, and not a branch of fact-knowledge, another thought, that looking on at various manufactories and writing an account of what had been shown and explained to them, was of more general value. The immense increase of crime in the United States among educated young men was cited by one who expressed an enthusiastic belief that the greatest check to it would be the organisation among children of societies for the prevention of cruelty to animals. Dr. B. Joy Jeffries read a paper on colour-blindness, urging that the three primaries are red, green, and violet; that blindness to the latter is so rare that practically colour-blindness means blindness to red or green; urging also the danger of persons with such deficiency being employed in many occupations, and the necessity of an experimental method of finding it out. The Fifth Circular of Information consists of information and suggestions with regard to the great educational department of the New Orleans Exposition now opening, at which gathering the Superintendents of Education are to meet in the ensuing year.

HERR JADRINTSOW of St. Petersburg is about to publish, in Russian and German, a work on the Uralo-Altai, and Ugro-Turanian tribes of Siberia.

ACCORDING to the *Colonial Mail* a statement comes from the Cape Colony which is deserving the attention of botanists. It is alleged that insects shun the land on which tomatoes are grown; and the cultivation of the *Lycopersicon esculentum* is accordingly recommended in all cases where it is possible to grow it—under fruit-trees, for instance, since the tomato will thrive in the shade of other trees, which few other plants will do—for the sake of the virtues attributed to it as a prophylactic against the inroads of insect pests. It would be interesting to know whether the tomato has been observed to exercise any such effect on insects elsewhere—in Canada, for instance, where the fruit is so popular—or whether it is only in warmer climates, like that of the Cape, that its peculiar powers are brought into play.

M. MARCEL DEPREZ, the well-known electrician, is not confining his labours exclusively to the transmission of electrical force to distant places. In conjunction with others he has patented a new telephone based on a new principle of vibration, and dispensing with the use of voltaic elements. The lease of the Compagnie générale des Téléphones being about to expire, the Municipal Council of Paris have held a protracted sitting on the question whether the lease should be renewed or not. In the course of the discussion it was proposed to grant the renewal of the lease provisionally for a month, in order to give the new apparatus a fair trial. The further discussion of the question has been postponed to the next meeting.

THE last number of the *Mittheilungen der deutschen Gesellschaft für Natur und Völkerkunde Ostasiens*, Heft 31, contains a paper by Mr. Knipping, on weather telegraphy in Japan, which has already been referred to in NATURE. Besides describing the agencies at present at work in connection with the Central Meteorological Observatory, Mr. Knipping suggests a reorganisation of service, especially as regards the lighthouses; the number of stations would then be eighty in place of twenty-four, and the increased value of the service for practical as well as for scientific climatological purposes would be proportionate. Herr Mayet gives the first part of a full and interesting description of his visit to Corea with the German mission which went there last year for the purpose of making a treaty. If continued on the same scale, it will be the most comprehensive and accurate account of Corea, its Government, people, laws, &c., yet published. When at the capital, Seoul, the members of the mission noticed, from a hill in the grounds of their residence, the extraordinary sunsets of October in that year; but no special observations were made, because they believed that the beautiful phenomenon was the usual accompaniment of fine weather sunsets in Corea. It is described as sometimes resembling the aurora borealis. Frequently it was

only a uniform brilliant brightness, the centre of which was the spot at which the sun had gone down; other evenings the sun shot rays like long fingers, of a darker colour, athwart the glow, and in one evening the change of the light and darker colours of the evening red were like the incessant wavings of the folds of a perpendicular curtain. The effect of the phenomenon on the ignorant and superstitious inhabitants of Seoul, was of more immediate importance to the writer and his companions than its scientific aspects. They regarded it as a sign of trouble, war, and misfortune. Heavy rain which fell soon after averted any disaster from this cause.

A COMMISSION has been nominated by the President of the French Republic to investigate the archæology of Tunis, and report on the best method of preserving the ancient monuments of that country. A considerable number of specially-qualified French scholars have been appointed, and M. Ernest Renan has been named President of the Commission.

A SARCOPHAGUS with four face-urns has been recently found at Garzigar, near Köslin (Pomerania), and has been sent to the Antiquarian Provincial Museum of the Pomeranian Antiquarian Society at Stettin. A similar discovery was made last year at Klein Barkow (another Pomeranian village). Round one of the urns there was placed a bronze necklace, consisting of a stout bronze wire supporting eight so-called spectacle-spirals as ornaments. Prof. Berndt has proved in his work on Pomeranian face-urns, that they are really of Greek origin, dating from about the years 100 or 200 B.C., when Greek agents or factors went to live on the shores of the Baltic in order to trade with their home country in amber, furs, &c. Prof. Lindenschmidt (Mayence) and Dr. Schliemann indorse this opinion.

THE Imperial Japanese Meteorological Observatory has (according to the *Japan Mail*) issued a volume containing a series of monthly weather summaries for the months March to December 1883, each summary being accompanied by a map. The first weather map in Japan was issued on March 1, 1883, and the compilation therefore begins with that month. The greater part of the issue is occupied by twenty maps, indicating the tracks of centres of areas respectively of high and low barometers for the ten months dealt with, copious notes prepared from the daily telegrams being also furnished. For each month there is given the number of areas of high and of low barometer, with a short synopsis of the course of each, the place and date of highest and lowest temperature and barometric pressure, the number of gales, heavy gales, and hurricanes reported, with their localities, the occasions on which rain or snow fell, and the number of warnings issued. Lists are also given of the lighthouses from which gales were reported. These summaries are followed by monthly meteorological tables and illustrative maps, commencing two months earlier, and extending therefore over the whole of the year 1883. In these we find the mean temperature, mean pressure, altitude and rainfall for each month at twenty-two stations, and at the end there is a similarly prepared table for the whole year. The series closes with maps indicating by different degrees of shading the rainfall over the various parts of the empire during the twelve months, the aggregate rainfall for the year being shown by similar means in a final map.

AT the meeting of the Royal Physical Society of Edinburgh, held on December 17, the following office-bearers were elected:—Presidents: Benjamin N. Peach, F.R.S.E., John A. Harvie-Brown, F.R.S.E., Rev. Prof. John Duns, F.R.S.E.; Secretary: Robert Gray, V.P.R.S.E.; Assistant Secretary: John Gibson; Treasurer: Charles Prentice, F.R.S.E.; Hon. Librarian: R. Sydney Marsden, F.R.S.E.; Council: Patrick Geddes, F.R.S.E., Frank E. Beddard, F.R.S.E., Johnson Symington, F.R.C.S.E., Andrew Moffat, John Hunter, F.C.S., Robert Kidston, F.G.S., A. B. Herbert, William Evans Hoyle, M.R.C.S., F.R.S.E., Prof. James Geikie, F.R.S., Prof. J. Cossar Ewart, F.R.S.E., G. Sims Woodhead, F.R.C.P.E., Hugh Miller, F.G.S.

WE have received the October number of the *Proceedings* of the Boston Society of Natural History. It contains a continuation of Mr. Crosby's paper, meeting the objections advanced by Dr. Wadsworth against the author's views of the stratigraphy of the Boston Basin. It also contains a description, by Q. E. Dickerman and Dr. M. E. Wadsworth, of an olivine-bearing diabase, from St. George, Maine; as also the beginning of a paper by Thos. T. Bouvé, on the genesis of the Boston Basin and its rock-formation.

MESSRS. MACMILLAN AND CO. will very shortly publish a translation of the work of Dr. Hertel of Copenhagen on Over-Pressure in Middle-Class Schools in Denmark, with an introduction by Dr. Crichton Browne.

THE additions to the Zoological Society's Gardens during the past week include an Indian Civet (*Viverricula malaccensis*) from India, presented by Mr. W. Getty; a Bengalese Cat (*Felis bengalensis*) from India, presented by Mr. G. T. Egan; a Grey Parrot (*Psittacus erithacus*) from West Africa, presented by Mrs. Whitelow; a Kestrel (*Tinnunculus alaudarius*), a Sparrow Hawk (*Accipiter nisus*), British, presented by Mr. T. E. Gunn; a Broad-fronted Crocodile (*Crocodilus frontatus*), a Nilotic Crocodile (*Crocodilus vulgaris*) from West Africa, presented by Mr. J. M. Harris; an Undulated Grass Parrakeet (*Melopsittacus undulatus*) from Australia, deposited; two Golden-winged Woodpeckers (*Colaptes auratus*), a Blue Jay (*Cyanocitta cristata*) from North America, a Black-tailed Hawfinch (*Coccothraustes melanurus*) from Japan, two Red-headed Finches (*Amadina erythrocephala*) from South Africa, two Banded Parrakeets (*Palæornis fasciatus*), from India, received in exchange.

PHYSICAL NOTES

SEVERAL new primary batteries are in the field, and there are more to come. An iron cell invented by Dr. Pabst of Stettin is finding great favour in Germany. Its electrodes are carbon and wrought iron dipping into a solution of ferric chloride. It is practically unpolarisable and self-regenerating. It works at the expense of iron and of the oxygen of the air, which is absorbed into the liquid, whilst ferric oxide is deposited at the bottom of the cell. Its electromotive force is about ·78 of a volt. The Pabst cell ought to prove of value for domestic electric lighting, as its internal resistance is low and its constancy remarkable.

ANOTHER primary cell has the peculiarity that the element consumed in the liquid is carbon. In this cell—the invention of Profs. Bartoli and Papasogli—the electrodes are platinum, and a compacted mixture of retort coke and Ceylonese graphite. The exciting liquid is hypochlorite of soda. The electromotive force is, however, only ·2 of a volt at the most.

M. JABLOCHKOFF announces another battery of great scientific interest. A small rod of sodium weighing about 8 grammes is squeezed into contact with an amalgamated copper wire and flattened. It is wrapped in tissue paper and then damped with three wooden pegs against a plate of very porous carbon. This completes the element. The moisture of the air settles on the oxidised surface of the sodium. It works without any other liquid. The E.M.F. is 2·5 volts, but the resistance is as great as 25 ohms.

M. LAZARE WEILLER has shown that the phosphide of tin, drawn into wires, possesses a higher electric conductivity than platinum or iron.

M. EMILE REYNIER has made some very interesting experiments on the maxima and minima electromotive forces obtained from cells of one electrolyte. For this purpose he constructed two cells, one for determining the maxima and one for determining the minima electromotive forces. His maximum cell consists in giving the positive electrode as large a surface as possible—about 30 square decimetres—while the negative electrode consisted of a wire of 3 mm. diameter. The positive electrode was bent round

in the form of a sharply corrugated circle, and the negative electrode was placed in the centre, so that the resistance should be low, it varied from ·2 to 4 ohms according to the liquid used. The E.M.F. was practically constant during its determination, as the current drawn from the cell was only about ·001 ampere. The minimum cell was of similar form to the maximum, only the positive electrode was in the centre and was a wire of about 0·5 mm. diameter, and the negative electrode was in the form of a cylinder. By using cells of these forms he was able easily to change either of the electrodes or the electrolyte. The method of determining the minima electromotive forces was to short-circuit the cell for several hours, and immediately on opening the circuit to determine the E.M.F. The following are some of the results that he obtained with an electrolyte of acidulated water, 2 parts in 1000 being sulphuric acid :—

Electrodes			E.M.F. in volts	
Negative		Positive	Maxima	Minima
Zinc,	ordinary	Carbon	1·22	0·04
,,	amalgamated	Carbon	1·26	0·226
,,	ordinary	Lead	0·55	0·144
,,	amalgamated	Lead	0·684	0·152
,,	ordinary	Copper	0·94	0·194
,,	amalgamated	Copper	1·072	0·272
,,	ordinary	Iron	0·429	0·309
,,	amalgamated	Iron	0·476	0·323
,,	,,	Zinc, ordinary	—	< 0·09
Iron		Copper	0·49 to 0·51	—

AN experimental reproduction on the screen of the phenomenon of the solar halo has been recently brought before the Physical Society of Paris by M. Cornu. M. Cornu also discussed the phenomenon of the pink corona which has been visible around the sun during the past few months. He thinks it has its seat in the atmosphere at an elevation considerably higher than the level of the cirrus clouds which give the common ring-halo of 22°. According to M. Cornu the polarisation of the sky has been "profoundly modified" by the present phenomenon, especially when viewed through red glass.

SIGNOR A. RICCO sends us a lengthy memoir on a new form of electro-magnet invented by him. It consists of a sheet of iron rolled into a spiral round an iron core, the convolutions being separated by oiled paper. The current traverses the coiled sheet, which thereby becomes powerfully magnetised. A spiral of forty turns of insulated copper wire is added outside. The lifting power of this magnet appears to be very great in proportion to its weight.

A PAMPHLET on the system of simultaneous telephony and telegraphy invented by F. van Rysselberghe has lately appeared from the pen of M. Ch. Mourlon, secretary of the Société belge d'Electriciens.

DR. E. VON FLEISCHL recently communicated to the Viennese Academy a paper on the double-refraction of light in liquids. Concentrated solutions of tartaric acid and of various sugars were employed, also certain active oils, in a compound hollow prism resembling a Fresnel's quartz combination in its general disposition. The research proves the existence of doubly-refracting liquids ; but they possess no optic axis. The wave-surfaces are in every case two concentric spheres.

CHEMICAL NOTES

ATTENTION was lately drawn in these Notes to Schiff's recent researches on the connections between the capillary coefficients of various liquid carbon compounds and the structure of the molecules of these compounds (see also NATURE, vol. xxx. p. 618). The same subject has very recently been examined by J. Traube (*Ber.* xvii. 2294). Traube thinks that the differences between the various capillary elevations observed by Schiff are too small to allow of trustworthy conclusions being drawn : he has therefore undertaken a series of observations with aqueous solutions of various classes of carbon compounds. Inasmuch as the capillary elevation of water in a tube of ·34 mm. radius is about 41·5 mm., while that of most liquid carbon compounds does not exceed 25 mm., Traube concluded that there will probably be well-marked differences between the capillary elevations of aqueous solutions, and mixtures of aqueous solutions, of definite concentration, of various compounds of carbon. The height in capillary tubes was determined for each solution for varying degrees of concentration, and the results are stated for equal weights of compounds in equal volumes of solution. From these results Traube draws the conclusions :—(1) The capillary elevation of the solution of a compound decreases as concentration increases ; the differences of elevation are not equal for equal increases in concentration. (2) The capillary elevations decrease in a homologous series of carbon compounds as molecular weight increases. (3) Isomeric compounds in solutions of equal concentration do not always exhibit equal capillary elevations. Schiff's generalisation, that the number of molecules of isomerides raised by capillary action is equal, does not hold good for aqueous solutions of isomerides. As in Traube's experiments the liquids examined were of equal concentration, it follows that the ratios of the capillary elevations are equal to the ratios of the masses of the dissolved compounds raised in the capillary tubes. Calling the capillary elevation h, and the specific gravity of the solution s, Traube considers the product hs, which he calls the capillary coefficient of the solution. The value of h is conditioned by the chemical constitution of the compounds examined. If m = molecular weight of compound in solution, then the difference between $\frac{h}{m}$ for solutions of two compounds, within certain limits of concentration, is a constant which depends only on the relative concentrations of the two solutions. The values of $\frac{h}{m}$ for an homologous series, dealing with solutions containing equal masses of the compounds in equal volumes, are referred to the value of $\frac{h}{m}$ for the first member of the series, and the differences thus obtained, when calculated for a tube 1 mm. radius, are called the *specific capillary constants* of the compounds in the series. The values of this quantity are almost wholly dependent on the nature of the solution, perhaps only on the nature of the dissolved substance, and are independent, within certain limits, for each homologous series, of the absolute concentration of the solutions, and are scarcely, if at all, dependent on temperature. Traube thinks he is justified from his experimental results in concluding that the differences between the capillary elevations of the solutions of two analogous compounds are in the same ratio as the molecular weights of the compounds. Thus, let h_α and h_{α_1} represent the capillary elevations of two solutions, of different concentrations, of the compound with molecular weight m ; and let h_β and h_{β_1} represent the capillary elevations of two solutions, of the same concentration as those of the former compound, of an analogous compound with molecular weight m_1. Then, according to Traube,

$$\frac{h_\alpha}{m} - \frac{h_{\alpha_1}}{m_1} = \frac{h_\beta}{m} - \frac{h_{\beta_1}}{m_1};$$

therefore

$$\frac{h_\alpha - h_{\alpha_1}}{h_\beta - h_{\beta_1}} = \frac{m}{m_1}.$$

If, therefore, h_α, h_{α_1}, &c., are determined, the ratio $\frac{m}{m_1}$ can be found ; and if m is known, the value of the molecular weight of the second compound (m_1) can be calculated.

GEOGRAPHICAL NOTES

WE are glad to see that at last there is some probability of the almost unknown but certainly interesting country of Tibet being opened up to outsiders. We know the frequent but unsuccessful efforts which Prjevalsky and others have been recently making to penetrate to Lassa. But now the *Times* Calcutta correspondent informs us that the Regent of the Tashu Lama at Shigatze has sent a most cordial reply to the letter which Mr. Macaulay despatched to him from the frontier through the agency of the Governor of Kambajong, and has also addressed a letter to the Viceroy. With these letters, besides the silk scarves which ordinarily accompany Tibetan correspondence, the correspondent understands he has sent some relics of the late Tashu Lama himself, and has asked Mr. Macaulay to send him a Tibetan-English dictionary and phrase-book and some scientific instruments. This is the first official communication received from Tibet for about a hundred years. The correspondent suggests that the Government should put our relations on a firm footing by sending at once a friendly mission in connection with the identification which takes place this year of the infant in whom Tashu Lama is supposed to have been born again.

THE town of Bhamo, in Upper Burma, the destruction of which by the Kakhyen tribes is reported from Rangoon, is one well known in the exploration of South-Western China in recent years. The route so often traversed from Shanghai to Rangoon by the Yangtsze, Talifu, and the Irrawaddy passes through Bhamo. It is mainly a trading town, from which the caravans start into Yunnan, as here the navigation of the Irrawaddy ceases. The first modern explorer to visit it was Mr. Cooper, the traveller "in pigtail and petticoats," who journeyed so courageously throughout South-West China during the Mohammedan rebellion. The Indian Government was disposed at that time to pay more attention to a trade route into Yunnan than they appear to have been recently, and the importance of Bhamo on the route from British Burmah was recognised by the appointment of an agent to reside there, and gather information useful for commerce in these regions. Mr. Cooper, the most competent man for the post, was selected, but the good work which he was doing was cut short by his death one night in his tent near Bhamo, at the hands of one of his Burmese guards. At Manwyne, not far on the Chinese side of Bhamo, Mr. Margary was murdered in 1876, when on his way from the Yangtsze and Talifu, to meet Col. Browne's expedition, which advanced from Rangoon along the Irrawaddy, through Bhamo. A year later it was visited by the Commission of English officials under Mr. Grosvenor, which went to inquire into Margary's death; and, on account of the place being within easy reach of Rangoon and Mandalay by the river, it has been frequently visited by officials of the Indian Government, such as Cols. Browne and Fytche and Major Sladen. The latter's journey had for its object the removal of dangers to traders on the route from the Kakhyens, and he succeeded in coming to an understanding with the chiefs to keep the route open. Within the last few years McCarthy, on his way from Shanghai by the Japanese route, and Colquhoun from the capital of Yunnan, passed through the town. It was a small stockaded settlement of Chinese and Shan traders, with a lower order of Burmese, and there is a French missionary station at the place, while some Americans are also engaged in missionary work there and at Mauwyne. The Kakhyens inhabit the greater part of North-Eastern Burmah, between the Irrawaddy and Salween, and live mainly on the trade between China and Burmah, either as brigands and robbers or as carriers on the river and roads. In addition, they appear to trade a little on their own account. The grounds of their destruction of the town are unknown, but it is probably due to their predatory habits, the comparative wealth of the town as a central trading station in the region, and the weakness and incompetence of the native government of Upper Burmah, especially in a wild and remote border-land, such as that in which Bhamo is situated, and of which it is the capital.

AN interesting expedition has been undertaken by Mr. Shaw, a naturalist and artist of Sydney, New South Wales. He proposes to make a canoe voyage down the Lachlan, Murrumbidgee, and Murray rivers, his object being to enlarge our knowledge of the interior river-systems of Australia, and of natural history. The cost of the expedition is borne by the *Town and Country Journal* of Sydney, in which the artist's sketches will no doubt appear.

WE learn from the Australian papers that Mr. E. M. Curr of Victoria has been engaged on a work on the customs, language, and origin of the aborigines of Australia. Portions of the manuscripts were, early last year, sent to England to be submitted to the Council of the Anthropological Society. The Society has expressed the opinion that the Government of Victoria should publish the vocabularies and a record of the customs of the aborigines, as, otherwise, valuable information might be lost for ever. It is expected that arrangements will be made for the publication of the work at the public expense.

REPORT OF THE LONDON SCHOOL BOARD COMMITTEE ON TECHNICAL EDUCATION

WE are glad to publish the following Report on Technical Education which has been presented to the London School Board. The recommendations contained in it were passed on December 18, 1884, with a small modification in No. 5. The only one which received any serious opposition was No. 6, which relates to the Swedish Slöjd system, but this ultimately passed by a majority of two to one.

(1) *Constitution of Committee*

On February 1, 1883, the Board passed the following resolution:—"That a Special Committee be formed to consider and advise how far the Board may facilitate Technical Education, or co-operate with those bodies that are carrying it on."

On February 8, 1883, the Board resolved:—"That the Special Committee on Technical Education agreed to by the Board on February 1, 1883, consist of the following Members:—Mr. Roston Bourke, Mr. Bousfield, Mr. Bruce, Sir Edmund Currie, Miss Davenport Hill, Prof. Gladstone, Mr. Heller, Sir Arthur Hobhouse, Mr. Lucraft, Miss Muller, Rev. Henry Pearson, Mr. Lee Roberts, Mr. Whiteley, Mr. Mark Wilks, and *ex officio* the Chairman and the Vice-Chairman of the Board."

At the first meeting Prof. Gladstone was appointed Chairman of the Special Committee. Nine meetings of the Committee have been held.

(2) *Information from Gentlemen*

The Committee commenced their deliberations by endeavouring to obtain information from gentlemen who were interested in, and had studied, the subject.

The following gentlemen accordingly attended the Committee by invitation, and gave their views on the subject:—Dr. Silvanus P. Thompson, Professor of Natural Philosophy at University College, Bristol; Mr. H. Trueman Wood, Secretary of the Society of Arts; Mr. Philip Magnus, B.Sc., B.A., Director and Secretary of the City and Guilds of London Institute for the Advancement of Technical Education, and one of the members of the Royal Commission on Technical Instruction. The statements of these gentlemen are set out in detail in the Appendix to this Report.

(3) *Information from School Boards*

The Committee also obtained information from the clerks of the Glasgow, Manchester, and Sheffield School Boards respecting the steps taken by these Boards respectively for the instruction of children in technical education.

Glasgow, Allan Glen's Institution.—At the request of the clerk of the Glasgow School Board, Mr. A. Crum Maclae, Secretary of Allan Glen's Institution, Glasgow, replied, furnishing information respecting the technical instruction in that institution, and inclosing—(1) a prospectus of the school for 1883-84; (2) a report of the proceedings at the distribution of prizes and certificates in December, 1882; (3) a copy of a paper on the "Relation of the School to the Workshop," read before the Philosophical Society of Glasgow in December, 1882, by David Sandeman, Chairman of the Weaving Branch of the Technical College, and E. M. Dixon, B.Sc., Head Master of the Institution.

Manchester School Board.—The Clerk of the Board, in reply to the inquiry of the Committee, furnished information to the effect that the Board have no present intention of starting a technical school; that this work had been taken up by the trustees of the Manchester Mechanics' Institute, who have converted that institution into a technical school; that the Board have introduced a lathe and a group of joiners' benches into class-rooms of two of their schools, and each scholar in the higher standards of the school takes his turn at the manual exercises, receiving one or two lessons a-week, a joiner being present to give the instruction. No extra charge is made for the instruction. One of the schools is the lowest under the Board, where two-thirds of the children are admitted free, the other being attended by children of artisans and small shopkeepers.

Sheffield School Board.—The Clerk of the Board gave particulars respecting the admission, the examination, the fees, the subjects of instruction, and the results of the Central Higher School established in that town. In the workshop attached to the school the practical work contemplated will include—(1) the production of simple but perfect geometrical forms to teach accuracy and skill in the use of tools; (2) the construction of models in wood for use as examples in model drawing; (3) the construction of simple apparatus to illustrate, by actual experiment, the principles of levers, pulleys, wheel and axle, the crane and strain on beams with different positions of load; (4) the mechanics of the roof, arch, and bridge; (5) for more advanced pupils the construction of apparatus illustrating lessons in machine construction, applied mechanics, building construction, and mechanical engineering. It is added that there is a system of scholarships by means of which from fifteen to twenty specially clever boys and girls will be enabled to pass from the

ordinary schools to the technical instruction at the Central Higher School.

(4) *Action of British Association and Social Science Congress*

The Committee were officially informed by the chairman that a resolution had been passed in 1883 by the British Association for the Advancement of Science requesting a Special Committee "to consider the desirableness of making representations to the Lords of the Committee of Her Majesty's Privy Council on Education in favour of aid being extended toward the fitting-up of workshops in connection with elementary day schools or evening classes, and of making grants on the results of practical instruction in such workshops under suitable direction." The said Committee waited to see the Report of the Royal Commissioners, and expressed their approval of recommendation (*d*), which practically covers the same ground. The Social Science Congress has made a presentation to the Education Department to a similar effect.

(5) *Recommendations of the Royal Commissioners on Technical Education*

During the deliberations of the Committee the second Report of the Royal Commissioners on Technical Education, containing their recommendations, was published, and the Committee submit, for the information of the Board, the recommendations as to public elementary schools, as follow :—

(*a*) That rudimentary drawing be incorporated with writing as a single elementary subject, and that instruction in elementary drawing be continued throughout the standards. That the Inspectors of the Education Department, Whitehall, be responsible for the instruction in drawing. That drawing from casts and models be required as part of the work, and that modelling be encouraged by grant.

(*b*) that there be only two class subjects, instead of three, in the lower division of elementary schools, and that the object lessons for teaching elementary science shall include the subject of geography.

(*c*) That, after reasonable notice, a school shall not be deemed to be provided with proper "apparatus of elementary instruction" under Article 115 of the Code, unless it have a proper supply of casts and models for drawing.

(*d*) That proficiency in the use of tools for working in wood and iron be paid for as a "specific subject," arrangements being made for the work being done, so far as practicable, out of school hours. That special grants be made to schools in aid of collections of natural objects, casts, drawings, &c., suitable for school museums.

(*e*) That in rural schools instruction in the principles and facts of agriculture, after suitable introductory object lessons, shall be made obligatory in the upper standards.[1]

(*f*) That the provision at present confined to Scotland, which prescribes that children under the age of fourteen shall not be allowed to work as full-timers in factories and workshops, unless they have passed in the Fifth Standard, be extended to England and Wales.

(6) *The Slöjd System of Handicraft in Sweden*

The Committee have received valuable information respecting a system of instruction in handicraft, which is largely adopted in the elementary schools of Sweden. Two mistresses under this Board, Miss Warren, head mistress of the infants' department of the Carlton Road, Kentish Town, School, and Miss Clarke, head mistress of the infants' department of the Campbell Street, Maida Vale, School, were allowed an extended summer vacation, in order that they might visit Herr Abrahamson's Institution at Nääs, near Gothenburg, in Sweden, where instruction is given in handicraft. This institution is established and maintained by Herr Abrahamson on his own estate, for the purpose of training teachers in the system, in order that the teachers may be able to carry it out in their schools.

The Governments of some other countries were invited to send teachers to Nääs to learn the system, and through Miss Löfving, formerly Superintendent of Physical Education under the Board, the invitation was extended to two mistresses of the schools of the Board. Hence the visit of Miss Warren and Miss Clarke during last summer. These mistresses have returned with diplomas received from Herr Salomon, the Director of the "Slöjd" Seminarium at Nääs, for having successfully completed the set of articles required for the first course of the system.

Miss Warren stated that during the two months leave of absence which had been granted to her and Miss Clarke, they had, at the invitation of Herr Abrahamson, visited his institution, with the object of becoming acquainted with his system of instruction in handicraft. The work done is carried out in wood, and the general term of "Slöjd" is applied to it. Working in wood is considered the most useful, as by working in this material the advantages claimed for the system are obtained more easily and completely than by the adoption of any other material. Miss Warren exhibited to the Committee forty articles in wood, selected from the 100 articles, forming the course of instruction, which she had made during her visit. The system of instruction is divided into what is called the "Nääs" system, from the estate on which it is carried out, and the "Artisan" system. The "Nääs" system differs from the "Artisan" in that it is not called a trade, the work, mainly in wood, being carried out under the superintendence of a *teacher*, and not being sold.

The work is done in a room fitted with benches, the room being about the size of one of our smaller halls. Only one teacher is in this room. The tools used all come from England and America. The cost of the tools per child is about 30 kronor, or 32*s.* 6*d.* The cost of the wood for 100 models is, *in Sweden*, about 15 kronor, or 16*s.* A complete set of the tools required could be obtained for about 4*l.* 10*s.*

The object of the system is not so much to produce the articles as to educate and train the child itself. The promoters of the system claim for it five distinct advantages :—

(1) It produces in a child a love of manual labour.

(2) It promotes the development and training of a child's hands and fingers.

(3) The child learns order and exactness.

(4) It educates a child's observation and perceptive faculties.

(5) It teaches self-reliance.

The school hours in Sweden are from 8 a.m. to 1 p.m., with an interval of a quarter of an hour about eleven o'clock. The instruction in "Slöjd" is usually taken in the afternoon. About two and a half hours on three days a week are devoted to this work. "Slöjd" is encouraged and paid for by Government, but is not compulsory. Children begin the work at about ten years of age. It is a punishment for a child to be withheld from it. Everything made is a *useful* article, the making of toys being prohibited. The articles when finished are given to the children as an encouragement. The child who does not succeed in the ordinary subjects of study is frequently encouraged on being successful in "Slöjd."

(7) *The Peripatetic System of Science Teaching in Birmingham*

In the course of their deliberations the Committee have noted and carefully considered the system of science teaching adopted by the Birmingham School Board. This system is sometimes called the "peripatetic" system. "The elementary science "is taught in accordance with a syllabus, by a practical demonstrator and assistant (who visit each boys' and girls' department once every fortnight), and by the teacher of the school. The Science Demonstrator for the Board (or an Assistant Demonstrator) gives one lesson fortnightly of about forty minutes' duration to the boys in the Fifth and higher Standards in each school. The lessons are illustrated experimentally by specimens and apparatus carried from school to school in a hand-cart. Between the visits of the Science Demonstrator at least one lesson is given to the same class by the teachers of the respective schools (as a rule by a teacher who was present at the Demonstrator's lesson, and took full notes of it), and a written examination on the subject-matter of the lesson is also held. The answers are corrected by the class teacher and submitted to the Demonstrator at his next visit to the school. A general examination in elementary science is held yearly." The syllabus for boys comprises demonstrations on force, the mechanical powers, machines, parallelogram of forces, &c.; and that for girls demonstrations on the structure of the human body, circulation and respiration, the organs of digestion, the nervous system, the nature of food and its preparation, apparatus for cooking, how to maintain the body in health, the sick room, diseases of children, accidents, &c.

(8) *Conclusions*

After considering in all its bearings the whole question of the introduction of technical education and training into the schools of the Board, the Committee are of opinion that there is at present too little instruction for boys which is calculated to train and exercise the hand and fingers, so as to fit lads more efficiently

[1] This recommendation will not apply to London schools.

for situations where skilled manual labour is required. In this respect boys are worse off than girls. It is only in the drawing lesson that the boys receive any training of the hand, whilst girls obtain it in the needlework and cooking lessons as well. The Committee do not consider it desirable to attempt to teach any special trade or handicraft in the schools of the Board; but they are of opinion that in boys' departments greater attention should be paid to the teaching of "elementary science" and to freehand drawings from models; that mechanical drawing and modelling in clay should be introduced; that the peripatetic plan of teaching mechanics should be tried as an experiment in some district in London; and that, as an experiment, arrangements should be made for the establishment of a class for the elementary instruction of boys in the use of tools as applied to working in wood, the attendance being voluntary and out of school hours.

The Committee desire to express their high appreciation of the services rendered by Mr. Thomas Smith, and the zeal with which he has assisted them in their work.

(9) *Recommendations*

The Committee accordingly submit for adoption the following recommendations, which are intended to apply to boys' departments only:—

(1) That it is not desirable to attempt to teach any special trade or handicraft in the schools of the Board.

(2) That the instruction in drawing commence with Standard I. and be carried out according to a graduated scheme laid down for each standard.

(3) That increased attention be paid to freehand drawing from models in all schools, and that mechanical drawing and modelling in clay be introduced into certain schools.

(4) That greater attention be paid to the teaching of "elementary science" in the schools of the Board.

(5) That the peripatetic plan of teaching "mechanics" be tried in some district or districts of London.

(6) That, as an experiment, arrangements be made for the establishment of a class for the elementary instruction of boys in the use of tools as applied to working in wood, the attendance being voluntary and out of school hours.

(7) That the above resolutions be referred to the School Management Committee, with instructions to carry them into effect.

(8) That the sum of 10*l*. be paid to Mr. Thomas Smith, Principal Clerk of the School Management Department, as remuneration for his extra services in connection with this Committee.

B. LUCRAFT
H. D. PEARSON

APPENDIX

Statements of Dr. Silvanus P. Thompson, Mr. H. Trueman Wood, and Mr. Philip Magnus

I. Statement of Dr. Silvanus Thompson, Professor of Natural Philosophy at University College, Bristol, made before an informal meeting of the Committee on Technical Education, April 17, 1883.

Prof. Thompson stated with regard to drawing, that in his opinion the drawing taught and paid for by results by the Science and Art Department was not of the character which he considered should be taught. The subject he wished to see taught was what he liked to call industrial drawing, by which he meant that a block of wood or metal being placed before the children, they should execute from it drawings showing it in two or three different ways, exactly in the fashion in which workmen's drawings are made. Drawings made to scale represented in the workmen's fashion would be very much more valuable than the drawings executed under the regulations of the Science and Art Department. Industrial drawing such as this may be made applicable to all kinds of work, carpentry, masonry, &c.

He then described a lesson on drawing given in Paris on the general mechanism of tools. The lesson consisted in the master sketching roughly on the blackboard the outlines of certain pieces of machinery. He had neither compasses nor ruler. Every line had a distinct meaning, and every single detail was labelled. The boys were then told to make proper working drawings from this sketch. This kind of training seemed to him a very valuable thing. To know how to "read" a drawing is much more important than to turn out a highly-finished work of art. The main difficulty in introducing such a system would be that it would have to be created. No instructor in technical education had yet made it worth his while to evolve a system.

Prof. Thompson suggested that a section of certain schools might be devoted to the teaching of handicrafts. Some of the ordinary handicrafts in wood or metal would be good subjects to commence with. It would be better to try the experiment in one small school unless the Board are prepared to go to a very great expense.

He considered that a good deal might be done in training the hand and the eye by the introduction of clay modelling. As illustrating the value of modelling in clay, he stated that in Paris the masters' union for the manufacture of jewellery had established a little school for teaching the knowledge and practice of art required in making jewellery. In this school there is modelling in clay and wax, drawing from the cast and from the flat, and also a little actual model work. Various works of art are hung round the room, and from the cast the pupils model in clay. After that there is a course of modelling in wax. The children are about nine or ten years of age. Some begin their attendance here as early as eight.

Cutting stone and carving in wood are good subjects. Plastering is merely pouring plaster into a mould, and mechanics is not of a very technical order. He doubted whether glass-blowing would be useful. The opinion of the union was greatly against the increase in the number of apprentices. Glass-blowing was taught at a disadvantage in England, because the union would not sanction each master having more than one boy.

The subjects that might be taught to girls are wood carving, vellum painting, the making of artificial flowers, and dress-making. Engraving would be expensive. A great deal of chain-making is done by female labour, but there is not much to learn in it.

He knew of no place where these handicrafts were carried on, with the exception of a few orphanages.

II. Statement of Mr. H. Trueman Wood, Secretary of the Society of Arts, made before the Special Committee on Technical Education, June 13, 1883.

Mr. H. Trueman Wood gave the Committee some informatio about the origin of the City and Guilds Institute for the Advancement of Technical Education, with the foundation of which he had been associated. The work which that Institute was now engaged upon the Committee would have more fully set before them by Mr. Magnus. He gave a brief sketch of the movement which, originating in a proposal to establish a Technical University in London, had resulted in the formation of the City Institute, with its "Central Institution" now in course of erection at South Kensington, and its Technical Schools in Finsbury and Lambeth. He also described the system of Technological Examinations which, originated by the Society of Arts, had been taken over by the Institute, and developed to its present condition by the aid of a scheme of payment on results, similar to that of the Science and Art Department.

Mr. Wood, in reply to various questions put by Members of the Committee, gave the following additional information:—As regards those who attended the school in Finsbury, he could not speak with any knowledge, but he did not think that the larger proportion of them were artisans; he believed they were chiefly clerks and young people of the usual science student class. Some of them, he understood, were boys from the Middle-Class School in Cowper Street. He did not know of any school where boys of the artisan class of twelve or fourteen years of age could go and learn the use of tools, and he was not aware of the existence of any such school in England. He stated that he was strongly of opinion that mechanical drawing should be taught in all elementary schools. The industrial training given in industrial schools was, of course, one form of technical education, but he should scarcely include this in what should be taught in elementary schools. He was of opinion that it was not possible to give definite technical instruction in elementary schools; the children were too young, and, in many cases, it could not be said which trade they would follow in after-life. He did not himself see how more could be done than was being done in Birmingham, where, he understood, practical teaching in elementary science was given to the children. Such teaching as this he believed to be most valuable, and the best possible preparation for the specialised technical instruction which would come later on. Elementary mechanics should certainly be taught and should be illustrated by suitable apparatus. He quite

agreed that general instruction in handicraft would be useful, teaching children the use of tools without reference to special trades, and, he believed, the experiment of fitting up a workshop in one school was one that was worth trying, and would not be, in his opinion, very costly. He left, as an open question, whether such workshop should be used in playtime, or during the ordinary school hours.

III. Statement of Mr. Philip Magnus, B.Sc., B.A., Director and Secretary of the City and Guilds of London Institute for the Advancement of Technical Education, and one of the members of the Royal Commission on Technical Instruction, made before the Special Committee on Technical Education, July 4, 1883.

Mr. Philip Magnus gave the following evidence:—

He stated that there is a double object in the establishment of the Central Institution, now in course of erection at South Kensington. On the one hand, it is intended to give the highest technical education to persons preparing to become engineers, manufacturing chemists, and managers of industrial works, and other persons engaged in scientific research in its application to particular trades. On the other hand, it is especially intended as a training school for technical teachers. The latter function of the institution is considered the more important, because the experience of all persons connected with technical education has shown that there is a great need of duly qualified technical instructors in all parts of the kingdom. It is very likely that arrangements will be made by which teachers will be able to come up to London in the summer months and to obtain lessons in applied science and in the best methods of technical teaching.

As regards the students who attend the Technical College, Finsbury, he wished to say emphatically that a large portion of them are artisans. There are indeed two classes of students who attend the Finsbury Technical College: one class coming in the daytime and the other in the evening. The evening students are almost all engaged in industrial work, and very few of them are clerks. Of those who attend in the daytime, he might say, none are clerks. A few have already been engaged in industry, and, feeling the want of technical instruction, have given up their trade to devote a year or two to study; but the great majority are youths who intend to follow industrial pursuits, and are carrying on their studies with that object. The total number of students in attendance at the College in the evening classes is 621, of whom 132 are apprentices admitted at half the usual fee. Of the day students there are at present about 100 in attendance, the school being opened under its present organisation only in February last. These students come from various middle-class and higher grade schools. A fair proportion of boys are expected to come from the Cowper Street schools, immediately adjoining the college. At the same time it is hoped that pupils will come to the College from other schools of the same grade. It is indispensable that the boys to be admitted should have a good knowledge of arithmetic and of the rudiments of mathematics; *i.e.* they should be able to solve simple equations and understand thoroughly the first book of Euclid.

In answer to the question whether the Finsbury Technical College could be made available to boys from elementary schools, Mr. Magnus said he saw no reason why boys from the higher grade of elementary schools, possessing a knowledge of elementary mathematics, should not be admitted into the College.

In answer to the Chairman, he said it would be well for candidates for admission to have some knowledge of the principles of science, although such knowledge is not absolutely necessary, as some of the Professors of the College stated that they would almost as soon commence the teaching of science as continue the instruction of badly taught students.

The limit of age for the admission of students is fixed at fourteen. Students entering at fourteen, having a fair knowledge of the elements of algebra and geometry, and an acquaintance with some of the principal facts of physical science, would be well able to go through the prescribed courses of the Finsbury College; and such knowledge might be acquired by boys who had passed through the higher Standards, and had taken mathematics and mechanics as specific subjects.

Mr. Magnus thought it would be preferable that boys leaving the Board Schools should be selected about the age of twelve or thirteen, and drafted into higher elementary schools where they might receive the necessary instruction in mathematics and science, and that they should be drafted from these higher elementary schools to the Finsbury Technical College.

The subjects taught at the Finsbury College are practical science, including physics, mechanics, mathematics, and chemistry, mechanical and freehand drawing, handicraft work, French or German, or both. In the workshops the students are taught to work in wood and metal at the bench and at the lathe. They learn not only the use of tools, but to chip, file, turn, and to construct simple apparatus.

(Mr. Magnus here put in evidence his address at the opening of the Finsbury College, as well as the programme of instruction.)

Apprentices and workmen attend the evening classes to learn the more difficult operations of their trade, and to gain an insight into the processes of which they cannot always obtain satisfactory explanation in the shop. It is to correct the effects of extreme division of labour that evening technical classes are most needed.

As regards carpentry and joinery, the institute is now endeavouring to devise a scheme of evening instruction in connection with the technological examinations, which will probably lead to the establishment of evening classes in this subject in several provincial towns.

Having been asked how the School Board might aid in the development of technical education, Mr. Magnus said that the Board might aid in various ways.

Instruction could be given in the elementary schools in machine drawing. Better instruction might also be given in freehand drawing, of the defects of which the institute's examiners in technology generally complain. In a large number of schools workshops might with advantage be established, in which a certain number of the more advanced boys might have the opportunity of gaining instruction in the use of tools, in the same manner as is done in the primary schools in France under the new Act. It would be a great advantage to the boys on leaving elementary schools, be their occupation what it may, to have acquired the facility of using their hands, and to have gained a knowledge of the properties of different kinds of wood, as well as of iron and other metals, which could only be obtained by working these substances themselves. By the establishment of workshops in schools, the boys, when apprenticed, would advance more quickly in their career, and reality would be given to their scientific instruction as well as to their lessons in mechanical drawing. He considered the great want of this country to be higher elementary or intermediate schools of a technical character. As regards the scheme of education to be given in such schools, he referred to his address on "Technical Instruction in Elementary and Intermediate Schools," delivered before the Society of Arts. He thought that scholars who distinguished themselves at the ordinary elementary schools should be sent to technical schools of this description in preference to such schools as the City of London School or King's College School. Here, in England, education is too distinctly and exclusively literary. We want schools in which practical science, mathematics, and modern languages shall be the chief instruments of education. It has been the object of the City and Guilds of London Institute partly to supply the deficiency by supplementing the existing educational machinery. The Central Institution at South Kensington will, doubtless, exert considerable influence on all schools leading up to it. It will show that there is a school of the same grade as the ancient Universities, giving a practical scientific training instead of a literary or theoretical education. The selected boys from primary schools should be led up to the Technical University or Central Institution rather than to the existing Universities, where they are too often drafted into professional careers which are already overcrowded.

In answer to an inquiry as to the view Mr. Magnus held as regards the value of the study of English literature in schools, Mr. Magnus stated that he attached the highest importance to the study of English literature in higher elementary schools as developing the imagination and giving pupils a taste for reading.

Besides mechanical and freehand drawing, pupils having a taste for art should be taught modelling, the study of which is not sufficiently developed in this country.

He considered that geometry should be taught practically without Euclid; whilst Euclid is very valuable to those who wish to become thorough mathematicians, he thought that very few of those who learn the elements of Euclid derive any practical benefit from the study. Abroad, geometry is generally taught without Euclid.

As regards the technological examinations, Mr. Mangus said that four years ago the institute took over these examinations from the Society of Arts, which had previously conducted them under somewhat different conditions. The candidates have increased very much during these four years, especially those in mechanical trades. At the time of the transfer of the examinations, the number of candidates was 212, whereas this year, 1883, the number of candidates amounted to 2397.

The Council of the Institute are very desirous that scholarships should be established in connection with the Finsbury College and other similar technical Colleges throughout the kingdom, to enable promising pupils to carry on their education at the Central Institution. If children could be taught sufficient mathematics and elementary science to be transferred from the Board schools to the Finsbury College, or to some other technical school, and thence to the Central Institution, he considered the ladder of technical education would be complete.

He thought that the Board might further aid in assisting technical education by the loan of its rooms for the formation of evening classes, it being always understood that, in order that the instruction should be of any use, it must be of a practical character, and that the classes should be well furnished with all necessary models, apparatus, &c.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

MR. THOMAS PURDIE, Ph.D., B.Sc., Associate of the Royal School of Mines, has been appointed Professor of Chemistry in the University of St. Andrews, vacant by the retirement of Dr. Heddle.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, December 4, 1884.—William Carruthers, F.R.S., Vice-President, in the chair.—The following were elected Fellows of the Society:—The Hon. F. S. Dobson, W. A. Haswell, Geo. W. Oldfield, Dr. G. W. Parker, M. C. Potter, T. J. Symonds, W. A. Talbot, and J. H. Tompson.—Mr. W. T. Thiselton Dyer exhibited:—(1) Examples of leaves of *Sagittaria montevidensis* under different modes of cultivation, the changes thus induced as regards size and general facies being most remarkable, so much so that they might be deemed widely separate genera. The small leaves were from a plant raised from seeds collected in Chili by Mr. J. Ball, F.R.S., and sent to Kew in 1883, and grown in a pot half submerged in the *Nymphæa* tank. The enormously large leaf and spike were those of a plant raised from seeds, ripened at Kew, and sown in spring (1884). When strong enough the plant was planted in a bed of muddy soil, kept saturated by means of a pipe running from the bed to the *Nymphæa* tank. (2) A special and peculiar instrument called a "Ladanisterion," from Crete, it being a kind of double rake with leathern thongs instead of teeth, and used in the collecting of gum Labdanum, a drug now dropped out of modern pharmacy. The instrument in question was procured for the Kew Museum by Mr. Sandwith, H.M. Consul in Crete. (3) A collection of marine Algæ from West Australia, brought to this country by Lady Broome.—A paper was read by Dr. Francis Day on the relationship of Indian and African fresh-water fish-fauna. In this communication the author refers to certain papers of his, read before the Society on previous occasions, but he more particularly deals with the differences shown between his own statements therein and those subsequently given by Dr. Günther in his "Introduction to the Study of Fishes." Dr. Day is inclined to believe that in the consideration of Indian fish distribution there seems a possibility that certain marine forms, for example, the Acanthopterygian *Lates*, the Siluroid family Ariinæ, and others have been included among the fresh-water fauna by Dr. Günther, whereas fresh-water genera, such as *Ambassis*, several genera of the Gobies, *Sicydium*, *Gobius*, *Eleotris*, &c., have been omitted from the fresh-water fauna of India by Dr. Günther. Thus Dr. Day attempts to show that there may be less affinity between the African and Indian regions, so far as fresh-water fishes are concerned, than there is between his restricted Indian region and that of the Malay Archipelago. He adds that of 87 genera found in India, Ceylon, and Burmah, 14 extend to Africa, 44 to the Malay Archipelago, whereas out of 369 species only 4 extend to Africa and 29 to the Malay Archipelago.—On the growth of trees and protoplasmic continuity, was a paper by Mr. A. Tylor, giving his experiments in the curvature assumed by branches, particularly those of the horse-chestnut. He pointed out that the terminal bud is constantly directed upward, but is straightened out at a later stage of growth. Further, he found that terminal buds, when directed by being tied against a tree-trunk or plank, invariably turned away from the obstruction irrespective of the incidence of light. When the growing points of neighbouring branches were turned directly towards each other, they mutually turned aside or one stopped growth. Some co-ordinating system was necessary to enable the parts to act in concert, and he attributes this to a continuity of the threads of protoplasm.—A paper was read on *Heterolepidotus grandis*, a fossil fish from the Lias, by James W. Davis. The author describes the specialities of this form, and remarks that the genus had been instituted by Sir Philip Egerton for certain forms closely related to Lepidotus, but differing in their dentition and scaly armature. The *H. grandis* has interest, among other things, in the attachment of the dorsal and anal fins with the series of well-developed interspinous bones, in the peculiar arrangement of the articular apparatus of the pectoral fins, and in the heterocercal form of the tail.

Chemical Society, December 18, 1884.—Dr. Russell, F.R.S., in the chair.—The following gentlemen were elected Fellows:—W. P. Ashe, Sir B. V. S. Brodie, Bart., J. F. Ballard, W. Briggs, M. T. Buchanan, W. G. Brown, H. M. Chapman, W. H. Eley, J. Frost, T. P. Hall, H. J. Hodges, H. Jackson, F. Johnson, J. D. Johnstone, G. F. Kendall, C. W. Low, F. M. Mercer, P. C. Porter, V. E. Perez, A. Rickard, K. B. B. Sorabji, R. B. Steele, H. Smith, E. G. Smith, C. Thom, W. Tate, P. C. Thomas, T. Wilton, J. H. Worrall, W. C. Wise, W. H. Wood.—The following paper was read:—Chemico-physiological investigations on the cephalopod liver and its identity as a true pancreas, by A. B. Griffiths. The author could not detect any bile acids or glycogen in this organ, but a ferment obtained from it by glycerine converted starch paste into sugar, and formed from fibrin, obtained from the muscular fibres of a young mouse, leucin and tyrosin, the latter body giving, with a neutral solution of mercuric nitrate, a red precipitate. It was announced that at the next meeting, January 15, Prof. Thorpe would read a paper on the atomic weight of titanium, and that Dr. Frankland would give a lecture in February on chemical changes produced by micro-organisms.

Royal Microscopical Society, December 10, 1884.—Rev. Dr. Dallinger, F.R.S., President, in the chair.—Mr. Crisp exhibited Dr. Cox's radial microscope, a simplified form of Mr. Wenham's stand.—Mr. J. Mayall, jun., exhibited a new stage which he had devised, in which the thin upper plate was abolished and a frame to hold the slide substituted, which is not liable to flexure.—Mr. Crisp also exhibited Ward's eye-shade, Bausch's adapter for a spot lens, and Kain's mechanical finger.—Mr. Rosseter's paper on the gizzard of the larva of *Corethra plumicornis* and its uses, and one of Mr. G. F. Dowdeswell, on variations in the development of a Saccharomyces, were read and discussed.—A communication was read from Dr. Cox, the President of the American Society of Microscopists, expressing scepticism as to the possibility of making sections of diatoms so thin as those claimed by Dr. Flögel, as recently published in the Society's *Transactions*.—Mr. Parsons exhibited the hydroid form of *Limnocodium Sowerbii*, the fresh-water Medusa which he had found in April last at the Botanic Gardens, Regent's Park.—Dr. Zenger's method of mounting diatoms so as to show both sides was explained, and some mounts exhibited.—Mr. Cheshire gave a *résumé* of his paper on some new points in the anatomy of the bee. It has long been known that the queen bee, in common with many insects, stores the spermatozoa she receives from the male in a small sac, which is called the spermatheca. A long chain of evidence has also satisfied entomologists that in some way these spermatozoa are transferred to those eggs which are to be converted into undeveloped females known as workers, but the manner of this fertilisation has not hitherto been demonstrated. By carefully dissecting out a spermatheca with its attachment to the oviduc[illegible] unbroken, and then by needle-knives cutting through the trach[illegible]a which incloses it completely, the spermatheca and its valve m[illegible] b[illegible] isolated. It is then seen to be accompanied by a long dou[illegible] gland having a centrally-placed duct, provided with a sphin[illegible]r muscle near its junction with the aperture of the spermathec[illegible]. The spermatheca itself carries a sphincter and three muscl[illegible] [illegible]o to aid and

one to antagonise its action. The glandular secretion acts as a vehicle for carrying the spermatozoa, as liberated, towards the oviduct. Another gland, previously unknown, now adds its secretion, and serves to bring the spermatozoa into proper separation from each other. The common oviduct is not a simple tube, as formerly supposed, but carries in its centre a pouch of delicate membrane, and very like the recurved tail of a lobster. Two muscles, having for their especial purpose the direction of the egg in transit to the ovipositor, carry the egg, if a worker is to be produced, into this central pouch, and bring it into contact with the spermatic fluid, when a spermatozoon enters its micropyle. If a drone or male is to be produced, it takes a lower path in the right or left oviduct, and a side path to the ovipositor, and so avoids the pouch and escapes fertilisation. Siebold's theory of parthenogenesis in the bee is thus anatomically demonstrated to be accurate.—Dr. Van Heurck's paper on the resolution of *Amphipleura* into "beads" was read, and gave rise to a long discussion.—The meeting resolved to send a contribution to the memorial now being raised in America to the late R. B. Tolles, the eminent optician.

Royal Meteorological Society, Dec. 17, 1884.—Mr. R. H. Scott, F.R.S., President, in the chair.—Mr. C. H. Cotton, Mr. S. A. Jolly, L.R.C.P., and Rev. C. J. Taylor, M.A., were elected Fellows of the Society.—The following papers were read:—On the reduction of temperature means for short series of observations to the equivalents of longer periods, by Dr. Julius Hann, Hon.Mem.R.Met.Soc. The author has recently carried out an investigation into the climate of the Alpine districts of Austria, and in doing so he has endeavoured to reduce the monthly and annual means of all the temperature observations from the districts in question during the interval from 1848 to 1880, and in some places to 1884, to the mean for the thirty years' period 1851 to 1880. In this paper Dr. Hann describes the methods he adopted to reduce observations at mountain stations for short periods to the equivalents of longer periods.—The diversity of scales for registering the force of wind, by Charles Harding, F.R.Met.Soc. The object of this paper is to call attention to the confusion that exists in the systems in use by various countries for registering wind-force, whether instrumentally or otherwise, and to show the need of action for improvement.—Report on the phenological observations for the year 1884, by the Rev. T. A. Preston, M.A., F.R.Met.Soc. The salient features of the weather during the period embraced in this report, viz. October 1883 to September 1884, were: the mild winter, the cold April, the hot August, and the long period of drought, which at the end of September began to be seriously felt. The general effects on vegetation have been: the prolonged existence of many of the autumn species, the great loss of wall-fruit, the failure of bush fruits, the plentiful supply of strawberries as long as they lasted, but the time was short; the good hay harvest, although it was light in quantity; the good corn crop, the unusually plentiful potato crop, and the great abundance of wild fruits.

EDINBURGH

Royal Society, December 15, 1884.—Mr. Robert Gray, Vice-President, in the chair.—Dr. Sang read the first part of a paper on the theory of the tides.—Mr. J. T. Cunningham gave a communication on the nature and significance of the structure known as Kupffer's vesicle in teleostean embryos.—Prof. Turner discussed the relation of the alveolar form of cleft palate to the incisor teeth and the intermaxillary bones.—Mr. T. Andrews, F.C.S., gave a paper on the apparent lines of force on passing a current through water.

Royal Physical Society, Dec. 17, 1884.—B. N. Peach, F.R.S.E., F.G.S., President, in the chair.—The following communications were read:—On *Loligopsis* and allied genera, by W. E. Hoyle, M.A. (Oxon), F.R.S.E., &c. The author reviewed all the species which have at various times been referred to the genus *Loligopsis*, and indicated the different genera to which they should be relegated; the genera *Leachia*, Lesueur, and *Taonius*, Steenstrup, were fully characterised; *Desmoteuthis*, Verrill, was considered, and shown to be synonymous with *Taonius*.—Mr. Hoyle also exhibited, with remarks, a specimen of *Strongylus contortus* (Rud.).—Mr. J. R. Henderson, M.B., of the Scottish Marine Station, Granton, read a communication on additions to the fauna of the Firth of Forth. Specimens were exhibited of forty-five species new to the district, including the following:—*Astrorhiza limicola*, *Halecium* sp. (probably new), *Ascandra variabilis*, *Tomopteris* sp., *Nymphon hirtum*, *Corophium tenuicorne*, *Nyctiphanes* (*Thysanophoda*) *Norvegica*, and *Podopsis Slabberi* (new to Britain).—Mr. F. G. Pearcey explained a method of hardening friable and decomposed rocks, sands, clays, &c., so that sections may be made of them for microscopical purposes. During the cruise of the *Challenger*, he said, there was obtained a large collection of oceanic deposits, whose structure could not be accurately determined without making transparent sections. On account of their extreme friability this was found impossible by the usual methods, and it was therefore necessary to find a mode of rendering them hard and compact. After many experiments and much labour, a method was devised which had proved successful, and which would be found of great service to mineralogists, geologists, and others, in the investigation of soft rocks. It consisted in the introduction of a foreign substance to cement the grains together, and so render the material capable of being cut into sections. The substance used for this purpose was a solution of gum copal in ether, the ether being evaporated after the material had been soaked in the preparation, and the residuum carefully dried. Mr. Pearcey minutely described the various processes to be followed, and exhibited specimens illustrative of the results obtained. Mr. Hoyle spoke of the necessity of having mud and ooze examined by the polariscope, and bore testimony to the value of the method of doing this, which was due to Mr. Pearcey's patience and perseverance.—A note on the breeding of the Marsh Tit (*Parus palustris*, L.) in Stirlingshire during the present year (1884), with exhibition of nest and eggs, was read by Mr. William Evans, F.R.S.E.—On abnormal dentition in a Dingo (*Canis dingo*), specimen exhibited, by Andrew Wilson, L.D.S.—Mr. A. Gray exhibited, with remarks, a live specimen of the Water Spider (*Argyroneta aquatica*) from Luffness Marshes.

DUBLIN

Royal Society, Nov. 17, 1884.—Section of Physical and Experimental Science.—Prof. J. Emerson Reynolds, F.R.S., in the chair.—After an introductory address by the chairman the following communications were read:—Notes on the aspect of the planet Mars in 1884, by Otto Boeddicker, Ph.D., communicated by the Earl of Rosse, F.R.S. The notes are accompanied by thirteen drawings of the planet, representing the following longitudes of Mars' central meridian:—(1) 12°·6 (March 23), (2) 24°·9, (3) 28°·3 (March 22), (4) 38°·0 (March 23), (5) 73°·0 (March 17), (6) 137°·8 (March 10), (7) 261°·8, (8) 267°·4 (April 2), (9) 279°·4 (April 1), (10) 286°·7, (11) 303°·2 (February 24), (12) 307°·6 (April 1), (13) 317°·4 (February 24). When compared with Schiaparelli's charts they admit of the identification of the following spots:—*South:* Sabæus Sinus, Deucalionis Regio, Thymiamata, Margaritifer Sinus, Auroræ Sinus, Mare Cimmerium, Hesperia, Syrtis Minor, Syrtis Major, and a trace of Œnotria or Japygia; *North:* Lacus Niliacus, Nilus, Alcyonius Sinus, Astapus; on the *disk-middle* traces of these canals: Gehon, Indus, Hydaspes, Ganges, Cyclopum, Phison, Euphrates. Sketches Nos. 1 to 4 show when the markings in longitude 10° lie on the disk-middle, the sp–nf direction of Deucalionis Regio, but when they lie near the preceding limb the sf–np direction of Thymiamata prevails so considerably that the angular shape of the two Sinus Sabæus and Margaritifer may be entirely overlooked, and only the one or the other direction perceived and ascribed to them. Lacus Niliacus is seen interrupted on Nos. 1 and 4, so as to resemble its appearance on Schiaparelli's chart of 1882; and Nilus is seen double on No. 13—which makes it probable that a trace of Schiaparelli's gemination of lines was perceived at Birr Castle. During the time between Nos. 7 and 8, Syrtis Minor became much darker, and Syrtis Major became visible; this, as it cannot be due to the planet's rotation, is probably due to changes in its own atmosphere. Alcyonius Sinus appeared much darker than either in 1879 or 1881. Sketch No. 5, which at time of drawing was considered difficult but fairly good, does not show any spots capable of certain identification. A comparison with other drawings of the same period may explain this.—On the volatilisation of zinc from German silver alloys at high temperatures, by A. R. Haslam; communicated by Prof. C. R. Tichborne. Alloys of known composition were heated in a current of hydrogen, and weighings taken at intervals of one hour. The chief loss in weight was found to take place in the first hour, and the loss was greatest in the alloys that were poor in nickel. The author concludes that nickel has the effect of retarding the volatilisation of the zinc.—On the analogy between heat and electricity, by Prof. G. F. Fitzgerald, F.R.S. It was

pointed out that the analogy, as usually drawn between heat and electricity, namely, to liken temperature to potential and quantity of heat to quantity of electricity, is not the true analogy, inasmuch as the product of temperature and quantity of heat is not of the nature of energy, and that the true analogue of quantity of electricity is quantity of entropy. In this case a non-conductor of electricity is a non-conductor of entropy, *i.e.* a non-conductor of heat. As the quantity of electricity is the same at all parts of a circuit, and as it requires a perfect heat-engine to transfer entropy from one temperature to another undiminished, conductors must be of the nature of perfect heat-engines. It was further pointed out that a molecular structure of ether similar to that of a gas could be assumed, the motions of whose molecules might be polarised in such a way by differences of temperature that, although no heat was conducted, it would be thrown into a state of stress which would explain electrostatic phenomena. It was explained that this was a step beyond that made by Maxwell in his "Electricity and Magnetism," where he avoids any hypothesis as to how electric displacement produces mechanical stress. The author stated, however, that the object of this communication was not to bring forward this doubtful hypothesis, but, by drawing attention to this analogy between heat and electricity, to prevent the danger at present imminent of its being supposed that the analogy between electric displacements and the motions of an incompressible fluid is the only analogy possible, and of this mere analogy being consequently mistaken for a likeness.—Howard Grubb, F.R.S., exhibited a star map photographed by the Rev. T. E. Espin.

Natural Science Section.—V. Ball, F.R.S., in the chair.—On a new species of *Halcampa*. This is the first recorded example of the genus in Ireland, and it proves to be a new species, for which the name *H. Andresii* is proposed. It was found at Malahide, Co. Dublin.—Mr. G. Y. Dixon exhibited a living and some preserved specimens of *Peachia hastata* from Dollymount Strand, Dublin Bay. This is the first Irish locality.—The Chairman exhibited geological maps of Canada and of the United States, with specimens of Laurentian rocks and minerals.

Paris

Academy of Sciences, December 22, 1884.—M. Rolland, President, in the chair.—On a new method of measuring the heat of combustion of carbon and organic compounds, by MM. Berthelot and Vieille. The present paper is limited to the determination of the heat of combustion for cellulose (coton) and the various carbons used in the manufacture of gunpowder.—Description of a microscopic element by means of which it may be possible to determine the various groups of Cynthiadæ, by M. de Lacaze-Duthiers.—Remarks on the "Cours d'exploitation des Mines," presented to the Academy by M. Haton de la Goupillière.—Remarks on the volume of the *Connaissaance des Temps pour* 1886 and the *Annuaire pour* 1885, presented to the Academy in the name of the Bureau of Longitudes by M. Faye.—Note on the indeterminate equation

$$x^2 - Ky^2 - z^n,$$

by M. Maurice d'Ocagne.—On the thermodynamic potential and the theory of the voltaic pile, by M. P. Duhem.—Description of a diffusion photometer, by M. A. Crova.—Note on the heat of combustion of the ethers of some acids of the fatty series, by M. W. Louguinine. The author's experiments lead to the general conclusion that the heat of combustion of an acid is perceptibly equal to that of the ether of the same acid, less the heat of combustion of the corresponding alcohol, regard being had to the number of molecules of alcohol in reaction.—Note on the α-ethylamidopropionic acid, by M. E. Duvillier.—Observations on the optic activity of cellulose in connection with M. Béchamp's recent communication, by M. Alf. Levallois—On the cutaneous anæsthetic action of the hydrochlorate of cocaine, by M. J. Grasset. It is shown that the hypodermic injection of 0·01 gr. of the hydrochlorate of cocaine produces in man a sharply limited zone of cutaneous anæsthesis without general phenomena, and with slight local consequences, although lasting long enough to perform a certain number of surgical operations.—Influence of the variations in the centesimal composition of the air on the intensity of the respiratory functions, by M. L. Frédéricq.—On the spinal bone in the series of vertebrate animals, by M. A. Lavocat.—Note on the constitution of the reticulate rhizopods, by M. de Folin.—On the Acari dwelling in the quill of birds' feathers, by M. E. L. Trouessart.—On the existence of phanerogamous Asterophyllites, by MM. B. Renault and R. Zeiller.—On the Kersanton formation in the Croisic district, Loire Inférieure, by M. Stan. Meunier.—On a phenomenon of crystallogeny in connection with the fluorine of the Cornet rock near Pontigabaud, Puy-de-Dôme, by M. F. Gonnard —Results of the analysis of the masses of boiled beetroot, made with a view to determining the quantity of chloride of potassium and nitrate of potassium contained in it, communicated by M. H. Lepley. The quantity of these salts in 100 kilogrammes of root was found to be :—

	Max. Gr.	Min. Gr.	Mean. Gr.
Nitrate of potassium	342	43	131
Chloride of potassium	217	65	143

Berlin

Physical Society, Nov. 21, 1884.—Prof. Neesen reported on a case of magnetisation produced by a stroke of lightning, the distribution of which had been examined by a former pupil of the speaker. The lightning had struck the clock of a church tower, and so strongly magnetised it that it was only by great force that the pendulum could be moved from its position of rest, while the clock had to be taken to pieces and the magnetised iron parts demagnetised by means of heat. The most strongly-magnetic part was a U-shaped piece of cast-iron, the two perpendicular and downward-directed legs of which bore the edges for the pendulum. The distribution of the magnetism in this piece of iron was as follows :—Not far from the lower ends (at about a third of the height) was a neutral point on both sides, the inferior piece on one side being north polar, on the other side south polar. On the side having the north pole, south polar magnetism was found above the neutral point, extending above the middle line and beyond, so as to take in about the upper third of the other leg. Thereupon followed an upper neutral point, between which and the lower neutral point of this side was found north polar magnetism. The two lower neutral points were the spots where the two legs of the U-shaped piece of iron were connected by a horizontal iron pin. Other effects of the lightning were not to be found either in the clock or on the church tower.—Prof. Neesen further produced a galvano-plastic high relief of iron, of a dull silver-gray, which in fineness of detail far surpassed the productions of the silver galvano-plastic art. The method by which this was produced was still kept secret by the manufacturer.—Prof. Lampe communicated some interesting results arrived at by his pupils in exercises in calculation. One problem was to calculate the attraction of a homogeneous mass of certain form on a material point of its surface, if the attraction of the same mass in globular form on the pole was equal to 1. The calculation was first made for a flattened ellipsoid, in which the attraction on the polar point was known to be greater than 1. With increase of oblateness the attraction increased up to a maximum, for which the magnitude of the attraction and the eccentricity of the meridian curves were calculated. After this maximum the attraction abated, with further increase of oblateness, and the eccentricities of those meridian curves were calculated for which the attraction was equal to 1, as also of those for which it was equal to 0·5. Similar calculations were made for the elongated ellipsoid. In this case the attractions on the polar point became continually less, and only the eccentricity of the meridians was calculated, in which the attraction was equal to 0·5. Another exercise was to calculate the attraction of a circular cylinder on the middle point of a terminal plane, when the relation of the radius, r, of the terminal plane to the height, h, changed. In this case, too, with a certain relation of h to r a maximum of attraction was found, which was more than 1 but yet less than the maximum in the case of the flattened ellipsoid. After this maximum the attraction declined as well with increasing h as with increasing r, and the two relations of h to r, in which the attraction was equal to 1, were found. Finally, in the case of the circular cones, the attraction on the apex was calculated, and here, too, the maximum was determined, being, however, less than 1, and the cone was determined in which the attraction on the apex was equal to the attraction on the centre of the fundamental plane.—Prof. Landolt described a simple contrivance used by him for recovering the products of sublimation. A test tube, of glass in the case of bodies easy to sublime, of platinum in the case of bodies difficult to

sublime, was closed at the top by a stopper through which passed two small tubes, one reaching to the bottom, the other coming out below the stopper. The first small tube was connected with the condenser, and by this means the tube became permanently cooled. The cold tube was let down into the vessel in which the substance to be sublimed was being heated, and the products were obtained on the outside of the little tube, from which they could be easily removed. By a platinum tube in the platinum retort the speaker received molybdenous acid crystals, and, by the heating of lime, microscopic lime crystals.—Prof. Landolt further described an arrangement of a sodium lamp for a polarimetric apparatus in which a uniformly bright flame was produced, and he also showed a theodolite with a glass scale, which could be read by transmission of the incident light, thus facilitating observation.

Physiological Society, November 29, 1884.—Prof. Waldeyer exhibited a microscope-stand which he found very practicable, both for the ease and security with which it enabled a microscope to be turned in any direction, and for the way in which it allowed the use of any system of lenses.—Prof. Du Bois-Reymond spoke on the difficulty of determining the blood pressure in the capillary vessels, and discussed the method he had adopted in his lectures for the presentation of correct views on this matter. As was known, the blood-pressure in the capillary vessels had hitherto been determined by placing a small glass plate on a spot of skin and then estimating the pressure that was necessary to render this spot void of blood. By this method, however, the elasticity of the inter-capillary tissues was left out of account, and the results were therefore vitiated, so far as the determination of the pressure in the capillaries was concerned. The exact state of the case, which it was difficult for any experimental examination to come at, was, in the first place, able to be determined only under ideal conditions. In the current of an incompressible and inexpansible fluid through a system of pipes under a given propelling force the rate of current was always in inverse proportion to the cross section, while, with the distance of the propelling force, the pressure abated at a rate proportionate to the resistance, *i.e.* it sank more rapidly in narrow, and more slowly in wide, tubes. If a tube were widened by splitting it into two branches of equal calibre, the proportions between lateral section, rate of current, and pressure remained the same. If, on the other hand, the bore became as large again as before, the rate of current sank to a half, while the pressure decreased but little. If, again, a capillary network were intercalated into the system of pipes, the rate of current fell only in proportion to the enlargement of the total cross section; the pressure, on the other hand, sank considerably on account of the resistance presented by the capillaries, and the curve of pressure showed a very steep decline in relation to the abscissæ of the zero-line. If the capillaries again merged into simple tubes, the cross section became less, the rate of current proportionally greater, while the pressure again sank but slowly. In the middle of the capillary system the pressure, in accordance with known laws, amounted to half the initial pressure. In the circulation of the blood the cross sections of only the larger arteries and veins were known; the cross section of the capillary system was unknown. Under the ideal conditions, however, which formed the basis of the above scheme this cross section might be calculated from measurable rates of current. Suppose the rate of current of the blood in the capillary vessels equal to 0·8 mm. per second, and that in the aorta equal to 500 mm. per second, then the current in the latter was 625 times as swift as that in the capillaries, and the cross section of the whole capillary system must be 625 times as large as that of the aorta, or the diameter of all the capillaries was twenty-five times as large as the diameter of the aorta. The curve of pressure sank slowly in the arterial system. In the capillaries the great resistance required a very considerable difference of pressure, and the curve of pressure sank, therefore, very considerably; to sink more slowly in the veins down to beneath the abscissa line, *i.e.* the pressure in the veins in the neighbourhood of the heart became negative. In the middle of the capillary system the pressure, in accordance with this view, was equal to half the pressure in the ventricle. Should the arteries in consequence of the contraction of their smooth muscle-fibres become narrower, the point where the pressure in the capillaries was equal to half the heart's pressure shifted nearer to the arterial system. If, on the other hand, contractions or obstructions occurred in the veins, this point came closer to the venous system. Such a presentation of the case gave a view of the conditions of cross section and pressure in the capillaries, and offered a basis for experimental investigations. A scheme of the same kind might be applied to the system of lymphatic vessels, for which the average pressure in the blood capillaries must be taken as starting pressure.—Prof. Fritsch related an optical phenomenon he had perceived during the microscopical examination of certain objects, a phenomenon he described as due to monocular stereoscopic vision. Certain pictures, in particular those of the transverse section of the principal nerves of the electric organ, made a decided impression of a funnel-shaped depression such as was otherwise obtained only in the binocular contemplation of the well-known stereoscopic figures. It was especially easy for him to receive this impression on moving his eye from side to side. By producing the arrangement he had referred to at the next sitting of the Society, he would ascertain whether other eyes received the same impression of the picture.

VIENNA

Imperial Academy of Sciences, December 4, 1884.—On the scientific usage of orthogonal axonometers, by C. Pelz.—On the mechanical theory of electricity, by T. Tanuschke.—On energy and coercive state in the magnetic field, by G. Adler. On the consumption of some foods in the intestinal tract of man, by H. Malfatti.—Contribution to a knowledge of some hydroproducts of cinchoninic acid, by A. Weidel and K. Hazura.—On the action of the sun-spectrum on the haloid compounds of silver, and on the raising of their sensibility to some parts of the spectrum by colouring-matters and other substances, by T. M. Eder.—Computation of the orbit of the planet Russia 232, by N. Herz.

SCIENCE AND SURGERY

FROM the earliest ages, the functions of the brain have been a fascinating study to cultivated minds, and the greatest intellects of all ages have occupied themselves in attempting to solve its difficult and complicated problems. With the ancients this was a favourite pursuit, and engrossed the thoughts and talents of their most illustrious philosophers. Owing to the absence of exact methods of scientific observation and experiment, the conclusions on this subject were for many centuries of a purely speculative character, and the errors and fallacies thus deduced have been handed down and accepted till comparatively recent times. Modern investigations have, however, thrown a flood of light on the question, and although much still remains in the dark, the former obscurity has of late years been brightly illumined by the lamp of science. The accumulated clinical experience of ages had left knowledge on the cerebral functions in a state of confusion and uncertainty, and owing to the obvious difficulties and complications associated with disease, the results, however significant, were at best imperfect. That the brain should be subjected to direct physiological experiment was, until modern times, never attempted. During the last generation only has the practicability of this been demonstrated, and numerous observers have, by direct operations on the brain substance of animals, arrived at new conclusions as to its functions, and greatly revolutionised our ancient conceptions on the subject. Evidence has also been given against the *noli me tangere* theory, and abundant proof has been adduced of the fact that the brain may be handled, irritated, or partially destroyed without necessary danger to life. One of the latest developments of this method of investigation has been the discovery of those centres in the cortex which preside over voluntary motion, which have been, more especially by Prof. Ferrier, differentiated and localised with great precision. This important knowledge has been arrived at by an extended series of experiments conducted on living animals, in which, by observing the several effects of stimulating or destroying limited areas of their brains, the different functions of these special localities have been determined. A topography of the cerebrum has thus been constructed, in which the various faculties have been mapped out, but these, unlike the illogical visions of the phrenologists, have stood the test of sceptical criticism and rigid experimental inquiry. Researches of a purely scientific nature, carried out only with the object of elucidating truth and advancing knowledge, without immediate prospects of material gain, have in this instance led to most important and useful practical advantage. Armed with the knowledge acquired on animals in the laboratory, the physician has been enabled to utilise at the bedside the conclusions thus arrived at for the service of human beings. Clinical experience combined with morbid anatomy had already enabled the medical man to suspect the presence of disease in the brain, but as to its precise locality he was formerly in doubt. Now, however, guided by the recent revelations of physiology, he is enabled to predict the position in a large number of cases with great certainty and precision. Evidence of this is afforded by the proceeding adopted in a case of disease, notice of which has lately appeared in the medical papers. It appears that a man presented a series of symptoms which enabled Dr. Hughes Bennett to diagnose a tumour of the brain, that it involved its cortical substance, that it was probably of limited size, and that it was situated at a certain definite spot. The skull was trephined over the suspected region; there a tumour was found and removed. On recovering from the immediate effects of the operation the patien was and continued for three weeks in a satisfactory condition. He was perfectly intelligent, his functions, except for certain defects of motion caused by the disease, were normally performed, and there was an absence of all the distressing symptoms from which he had formerly suffered and from which he must necessarily soon have succumbed. Unfortunately, at the end of this time a complication, incident to all serious surgical operations, supervened, from which the patient ultimately died. The unhappy termination of this particular case does not in any way detract from the importance of the principles which it involves. It still remains a signal triumph of diagnostic accuracy, a precision mainly attained by exact experimental research. It is, moreover, further proof that by utilising this improved knowledge the surgeon may not only remove disease from the brain, but that he may do so without necessary shock or risk to the nervous system, and that the procedure, under modern antiseptic precautions, need not be attended with greater danger than may follow any other severe surgical injury. This interesting and instructive case will doubtless inaugurate a new era in medical practice, for although this particular individual has succumbed to measures adopted to avert his otherwise certain death, the experience thereby gained is sufficient to encourage further efforts in a similar direction which may prove beneficial to others. In the Marshall Hall oration of last year Prof. Ferrier remarked, "There are already signs that we are within measurable distance of the successful treatment by surgery of some of the most distressing and otherwise hopeless forms of intercranial disease, which will vie with the splendid achievements of abdominal surgery." He further added, reflecting on the success which had attended brain operations on animals, "I cannot but believe that similar results are capable of being achieved on man himself." That distinguished physiologist cannot but feel gratified that his prophetic words have been partially realised.

DE BARY'S "VEGETATIVE ORGANS OF THE PHANEROGAMS AND FERNS"

Comparative Anatomy of the Vegetative Organs of the Phanerogams and Ferns. By A. De Bary. Translated by F. O. Bower and D. H. Scott. (Oxford: Clarendon Press, 1884.)

IN 1861 a plan was drawn up in Germany to provide a series of hand-books or text-books on botany, which should treat of the science as it existed at the time; four of these books were completed, De Bary's "Vergleichende Anatomie der Vegetations-organe der Phanerogamen und Farne" (published in 1877) being one of them. This

book, as is well known, proved to be a masterpiece of industrious research, accurate treatment of facts, and critical sifting of details; its influence soon became apparent, not only on the best teaching and text-books of our time, but also on those engaged in original research in various directions. This marked influence was not confined to Germany, but affected the teaching in this country also; and some of us were so fortunate as to come under that influence before more antiquated methods of treatment had rendered difficult the task of receiving the new impressions.

Mr. Bower and Dr. Scott have now prepared a translation of this treatise, and those best acquainted with the original will be foremost in congratulating them, not only for having placed the work in the hands of English workers and students, but also for the manner in which it has been accomplished.

In commenting upon the plan of the book, it should be borne in mind that the basis of classification is anatomy, and anatomy only, and this accounts for many peculiarities in the mode of treatment.

The introduction sets this forth clearly, and shows the kind of difficulties to be avoided in the scheme. Students will gain by carefully reading this able introductory portion, which contains an admirable account and criticism of the relations of the tissues to the meristem from which they are derived, and the vexed question as to the best mode of classifying the systems of tissue in mature parts. The great difficulty of course is in the case of what Sachs terms the "fundamental tissue"—*i.e.* the tissue which remains after the dermal tissue and fibro-vascular system have been removed. De Bary finds it necessary to cut this up into several forms and systems of tissues, as was to be expected from the mode of treatment. Sachs has lately again maintained that on the whole the "fundamental tissue" is best regarded as one system. This and other discussions as to the relative value of systems of tissues certainly owe much to the point of view started from, and it is not easy to see how De Bary could avoid the further dissection of the larger systems of tissues.

As matter of fact he is constrained to adopt six chief forms of tissue, various groupings of which constitute the systems of tissues. These are: (1) Cellular tissue (epidermis, cork, and parenchyma); (2) sclerenchyma; (3) secretory structures; (4) vessels (this word is *Tracheæ* in the German, and "vessels" does not express its intended meaning accurately); (5) sieve-tubes; (6) milk-tubes (*i.e.* laticiferous vessels). Intercellular spaces forming the subject of an appendix. This preliminary classification, as would be expected, presents difficulties here and there, and it will be seen that the structures designated "secretory" afford exercise for the utmost ingenuity in classifying them anatomically.

Having laid down the lines along which the plan of the work is to run, so far as these forms of tissue are concerned, De Bary then proceeds to review and criticise the views held as to the differentiation of the various groups of tissues from definite layers or portions of the meristem of the growing-point. Hanstein's classification into dermatogen, plerome, and pleriblem is well known, as is also the calyptrogen of Janczewski. We cannot here enter into details, but must refer the student to this excellent summary, merely stating that the facts do not allow of Hanstein's classification being extended to all the cases, though it must be admitted as true for very many. Nor have later investigators succeeded in establishing a system of classification of the tissues comparable to that of the animal embryologist. This of course complicates the matter, and accounts in part for the plan followed in the second part of the book, which treats of the arrangements of the forms of tissue referred to above, and of the changes in their primary arrangement brought about by secondary changes, *e.g.* growth in thickness, &c.

In Part I. the first chapter deals with cellular tissue, the portion concerned with the epidermis and its structure being particularly interesting and important. De Bary's account of the stomata has long been known, but many facts relating to those peculiar forms known as water-pores or water-stomata will be new to the student unacquainted with the original. The description of the cuticle and cuticularised layers of the outer walls of the epidermal cells, and the facts as to the occurrence of wax on their exterior are very important, and must afford the basis for all future work on these subjects. A striking example of De Bary's critical power and ability to deal broadly as well as in detail with large series of facts are evident in his remarks on those troublesome organs known as glands. It may well be doubted whether we shall ever have a satisfactory classification of the various "secretory structures" on anatomical grounds solely; it must be admitted, however, that the most satisfactory account of these bodies, as a whole, is given in the present book. De Bary limits the term gland to epidermal secretory organs—all others are to have definite names implying their different position, &c. This necessitates the separate treatment of reservoirs of secretions, and laticiferous vessels as contrasted with epidermal or dermal glands on the one hand, and intercellular spaces which contain secretions, &c., on the other; the difficulties arising from various causes are in part met and discussed, but there are some still outstanding.

Having treated of the forms of tissue in the first seven chapters, Part II. of the book commences with Chap. VIII. The first section (Chaps. VIII. to XIII.) is concerned with the primary arrangement of the forms of tissue. The vascular bundles are here dealt with in great detail from two points of view: (1) with reference to their course or distribution in the stems, leaves, and roots; and (2) as regards their structure. The first aspect of vascular bundles is almost unknown in England, and most teachers have ignored it altogether. It is important, however, and although they must not be ranked or compared with structures occurring in other organisms, we must not forget that the supporting and conducting systems of a higher plant are represented by its wood and tracheæ, while its sieve-tubes have equally important duties to perform. This being so, there is no less reason for studying the course and distribution of the vascular bundles (and the same remark applies to laticiferous vessels, reservoirs of secretion, and even strands of sclerenchyma) in a plant, than for tracing the distribution of the various conducting, supporting, and secreting tissues and organs in a higher animal. Already the investigations promise to bear fruit, as witness Koch's descriptions of the course and endings of sieve-tubes in the leaves, and also the various points of anatomy which throw light on

the discussion as to the ascent of water in wood. No doubt it is too early to anticipate where these researches may lead; meanwhile every botanical student should learn the course of the vascular bundles in several typical plants, say, among others, *Lathyrus*, *Clematis*, a Palm, *Tradescantia*, a Fern such as *Aspidium*, and *Equisetum*. This should be done not only with reference to the distribution of these important structures, but also in order that the study of transverse sections may become something more than the impression of a pattern on the memory, as it too often is.

The bearing of these matters on the older views which confined the attention too much to the typical palm-type for the Monocotyledons, and to a few restricted examples of Dicotyledonous stems is obvious.

Some very important points exist also with reference to the structure of the vascular bundles, a matter which should be studied as De Bary studied it, in connection with the above. Students are seldom led to understand that the terminations and interconnections of vascular bundles often differ considerably from the enlarged portions of the bundles, or "bundle-trunks," as the translators term them. The classification of vascular bundles into collateral, concentric, and radial has become better known of late years; but even now too little attention is paid to the subject of the structure and development of the vascular-bundle system in roots. This should be all altered now, for it is difficult to imagine better guidance for teachers and students than is afforded by the work under review, and specialists will not be able to dispense with it.

Want of space prevents our entering further into some other weighty matters in this portion of the work. No doubt some difficulty will be felt by the uninitiated with regard to De Bary's treatment of the subject of sclerenchyma. The key to the difficulties consists in the fact that however convenient it may be to regard the sclerenchymatous fibres of the "hard-bast" as part of the "fibro-vascular" bundle, sclerenchyma may be regarded as a form of strengthening tissue which recurs in various positions, and may therefore be treated separately—that which occurs as strengthening tissue associated with the vascular bundles being called bast-fibres, and treated as part of the bundle (which then becomes "fibro-vascular") for no other reason than because it is convenient, and the name is an established one. Simple as the matter is when understood on anatomical grounds, we fear that confusion will still ensue from want of care in apprehending the state of the case; this will be due to no fault on the part of the translators, however, for the portions of the book dealing with these particulars leave little to be desired.

The second section of Part II., treating of the secondary changes produced in the arrangement of the tissues by growth in thickness, forms a part of the book which has had much influence on text-books since it was written. The account of the growth in thickness by means of a cambium zone is excellent, and should be carefully studied by every botanist. The concluding portions of the book are in some respects more adapted for the specialist than for the ordinary student, but we do not advise the latter to neglect them on that account; on the contrary, much of the foregoing information becomes clearer when contrasted with the more abnormal processes observed in the forms there treated of. The facts are somewhat more isolated, however, and can only become important in proportion as the earlier parts of the book are understood; moreover, work remains to be done among the more anomalous forms.

Enough has been written to show that no botanist will be able to dispense with the work, and it only remains to point out one or two faults in the translation, and perhaps to mention a few trivial matters which might have been put better. Such phrases as "a numerous group of large . . . cells (p. 21), "the morphologically lower leaf-surface" (p. 319), and "quite a few rows" (p. 372), are somewhat harsh, and result from the close rendering of the original; objection may also be taken to such employment of compounds as "air-and-water-containing" (p. 210) and "many-layered, chlorophyll-containing parenchyma" (p. 226). It is true that students of science who read much German find less difficulty from the recurrence of such forms in English than might be expected, but many will regard them as serious blemishes which render the book more difficult to read. *Commelyna* (p. 40) becomes "*Commelina*," subsequently (p. 270 *e.g.*) we believe the former is correct, the latter being the German spelling. "Equiseta" and "Gramina" (*e.g.* p. 213), and "*Orobanches*" (p. 384) are not elegant. The reference to Fig. 207 on p. 467 is wrong, that figure concerning *Cytisus*. No doubt the misprint stands for 209.

The translators are responsible for several terms which will be new to English botany, and we must admit our indebtedness to them for attempting to introduce definite English equivalents for such terms as "*Bündel-stämme*," "*Holz-stränge*," "*Neben-zellen*," and "*Ersatz-faserzellen*." Whether "bundle-trunks," "ligneous bundles," "subsidiary cells," and "intermediate cells" respectively will be generally accepted as the equivalents in English remains to be seen. Personally we regard them with favour, as serviceable representatives of terms which have their uses. However, we can do no more here than congratulate the translators on having placed one of the most important scientific works of the day in the hands of British botanists in a satisfactory form; and we no less heartily congratulate those botanists who have been debarred from reading it in the original German on the rich store so well placed before them.

OUR BOOK SHELF

The Solar System. By Ernest R. G. Groth, M.D. Pp. 34. (London: John Bale and Sons, 1884.)

THIS book contains a very imperfect account of the nebular hypothesis of Laplace and Kant, with certain variations which must be incorrect, because they violate mechanical principles, and with certain speculations which are valueless because they are based on mere imagination.

The author does not realise the relativity of force and motion, for on p. 9 he asks: "If a body be acted upon by no force, why should it move at all?"

On p. 11 we learn how axial rotation originates when a nebular mass revolves orbitally about a centre of force. The explanation depends on the different orbital motion of the nearer and further parts of the nebular planet. As far as this goes it should, when properly applied, give us

negative rotation in the planetary mass, but we here find it used to explain positive rotation.

The author states that the planets are "hurled" or "projected" from the sun: but he does not see that even if some *deus ex machinâ* were just to prevent the otherwise inevitable fall back into the sun, the eccentricity of the orbit must be very large instead of very small.

On p. 14 we find that "it is moreover manifest that each individual planet must from time to time have had its orbit greatly extended" by the reduction of the sun's mass on the birth of each planet. It is, however, the fact that the orbit of Jupiter, for example, would be scarcely appreciably altered were this process reversed, and were all the planets interior to Jupiter either suddenly incorporated with the sun or annihilated.

On this same page we learn "that in a system of particles revolving about a fixed centre, the momentum, that is the sum of the *products of the mass of each into its angular velocity* (sic ital), and the distance from the common centre is a constant quantity." Does it not follow that when a planet moves in an elliptic orbit, so that its distance from the centre of force is *not* constant, there is *not* constant moment of momentum? What then becomes of the generally accepted conservation of areas in elliptic motion?

The fanciful explanation of the inclinations of the planetary orbits, and of the obliquity of the planetary axes, need not be stated; but we observe that "the northern hemisphere, being that which contains more land than the southern, was directed away from the sun at the time it (the earth) was projected away from that body," and this, together with the context, shows that the northern hemisphere is here supposed to be heavier than the southern. The fact of course is that the hemisphere antipodal to Spain, by its greater density, attracts the sea away from the Spanish hemisphere and leaves our half of the globe drier than the other half.

The asteroids arise from the rupture of a planet X, which in cooling had been converted into a vast Rupert's drop (p. 21): "What a scratch does for the Rupert's drop, the pull occasioned by Jupiter's attraction effects for the doomed planet: the thin crust is rent, and forth in a thousand different directions fly his meteoric fragments."

On p. 23 we find that the Glacial period was a sudden catastrophe, and that the fleeing mammoths were caught by the intense cold and frozen to death.

At the end of the work the author emphasises the analogy, long ago pointed out, between the system of Saturn and his satellites and of the sun and his planets.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Apospory in Ferns

My note in Nature (p. 151) on the remarkable mode of reproduction in ferns discovered by Mr. Druery has brought me two friendly communications, both of which deserve a few words.

Dr. Vines reminds me that in an article on the proembryo of *Chara*, published in the *Journal of Botany* (1878, pp. 355–363), he had suggested that this structure is homologous with the spore-bearing generation (sporophore) in mosses. His arguments in favour of this view are extremely ingenious, if not wholly convincing. At any rate, if his theory is correct, the sporophore in this plant remains in a rudimentary condition, "producing no spores, but giving rise to the oophore by the lateral budding from one of its cells." Hence, he concludes, "we may speak of this plant as 'aposporous,' using a word which is symmetrical with the term 'apogamous,' applied by De Bary to those ferns in whose life-history no process of sexual reproduction occurs." We must give Dr. Vines, I think, the credit for first clearly defining in terms the aposporous condition as the converse of apogamy, though the phenomenon was first observed by Pringsheim in the Moss in 1876 (*Monatsb. d. Königl. Akad. der Wiss. zu Berlin*, 10 Juli, 1876). At any rate, according to Dr. Vines's view, what is only an occasional abnormality in the moss and the fern is the normal state of things in *Chara*.

The distinguished Italian botanist and traveller, Signor Odoardo Beccari, points out to me that the structures now known as archegonia and antheridia had been observed in *Salvinia natans* as early as 1834 by Savi. I had not overlooked the paper in which priority for the discovery was claimed for Savi by Marcucci (*Nuovo Giorn. Bot. It.* i. pp. 198–208). But the brief chronological table which I gave in my note had reference only to ferns proper (*Filices*) and not to the heterosporous group of the *Filicinæ*—the *Rhizocarpeæ*.

Frost Formation on Dartmoor

On the afternoon of Tuesday, December 30, 1884, about 3 p.m., we were on Yes Tor, near Okehampton, long reputed the highest point of Dartmoor, though it is understood that the new survey now in progress brings out the neighbouring summit of High Willhayse a few feet higher. For about 200 feet below the Tor the ground was frozen hard. It was free from snow, the weather having been fine for several days, but everything was white with hoar-frost. On the rocks of the Tor this frost assumed a form of singular beauty, and, we think, not a common one. At least, neither of us can match it in either English or Alpine experience, or remember to have seen an account of anything like it.

On the first impression the walls of the granite masses which make up the Tor looked as if covered with feather-work exquisitely wrought in congealed snow. The feathers (to call them so provisionally) overlaid one another as thickly as real plumage, and ranged in length from one inch or less to five or six inches, being smaller on the flat and recessed surfaces of the rock, and larger on the jutting and exposed ones. They lay almost wholly on the eastward, that is (as the weather then was, and for some days had been) the windward side of the Tor; and their tips pointed roughly in that direction, with the sort of uniformity one would get by laying down a great number of branches or feathers all one way. It is impossible to describe the richness of this natural decoration. Only the finest Oriental workmanship could come near the effect produced by the infinite and minute variety which this tapestry of frost-flakes combined with one dominant form and direction. Something of the same type, but far less perfect, may be seen on a mussel-covered rock at low water. Still more curious was the appearance of the Royal Artillery flagstaff which surmounts the Tor. It was loaded (on the windward side, like the rocks) with a solid fringe of the same formation, but in longer and thicker flakes. We judged it to be full six inches deep, and at first thought it must be supported by a string attached to the staff, but there was, in fact, no string at all.

Close examination of the individual flakes revealed great beauty of structure. They were mostly of an elongated lozenge shape, like a squared spear-head, but sometimes more like tongues of flame. Their contours and delicate surface-markings showed them to be built up of laminæ, into which they were easily resolved by a slight blow. These laminæ again split up into crystalline needles parallel to the longer diameter of the flake, that is, in the line of the imaginary spear-shaft. Only photography or very careful drawing (for neither of which had we the means, time, or skill) would clearly convey the details of the formation.

As to the physical explanation, we conceive that the process must have been set up by a thin layer of mist (probably in a very finely-divided state to begin with) drifting against the rock and freezing to it. Successive accretions brought in the same way would gradually produce the display of giant hoar-frost which we have imperfectly described. The details of form and structure we leave to be considered by those who have made a special study of ice-crystals. But it seems fairly obvious that for such a result there must be a concurrence of many favouring conditions. There must be a clear frost without snow, which of

course would destroy and obliterate these delicate forms. There must be a steady set of wind, enough and not too much of it, and the air must be saturated with moisture in a certain state of molecular division. Some of these data might, perhaps, with the resources of a modern laboratory, be settled by experiment. If the experiment succeeded it would be an extremely pretty one.

Krukenberg's Chromatological Speculations

MY attention has been lately called to a recent publication of Dr. C. F. W. Krukenberg, entitled "Grundzüge einer Vergleichenden Physiologie der Farbstoffe und der Farben," in which some remarks and misstatements occur relative to my work, which in self-defence I feel I am not justified in letting pass without comment.[1]

(1) With regard to his observations on the colouring matter obtained by me from the integument of certain invertebrates, and which I called "*dermochrome*," I do not see why I should have left it unpublished because three-quarters of a year before he had found that "lipochromes" were widely distributed in the animal kingdom. I found that lutein and hæmatoporphyrin occurred together in a peculiar combination, and said so. I suppose the offence lies in the name "lutein." This word must now, according to Krukenberg, be got rid of, because he has chosen to call it "lipochrome." Perhaps, after all, "lutein" is more appropriate, as it does not mean fat pigment; for this pigment occurs where there is no fat, *e.g.* it is not derived from fat in the *Corpora lutea.* Krukenberg bases his conclusions mainly on the reactions of the solid pigment with nitric and sulphuric acid and iodine, but I hope to have something to say on this point before long.

(2) Krukenberg maintains that the chlorophyll of cantharides is due to that in the intestines of these beetles. He committed himself to this theory at an early stage of his investigations, *before he knew of Pocklington's observations*; but after seeing the abstract of my paper read at the meeting of the British Association at Southport in 1883, in which I called attention to Pocklington's work, he makes it appear that he knew all about it long ago, which is not fair. Now since Pocklington and I obtained chlorophyll from the *elytræ* of these beetles, I do not think the above theory can be accepted, except it can be proved by Krukenberg that the intestine ramifies through the *elytræ*.

(3) Krukenberg says that *I* "*assume*" that the chlorophyll spectrum seen by me in the integument of the larva of *Pieris rapæ* is due to chlorophyll in that situation, whereas it is really due to chlorophyll-holding masses in the intestine. I never did "assume" anything of the sort. I said distinctly at Southport that it was due to food chlorophyll in the intestine, as could easily be proved, for on emptying the intestine the chlorophyll band could no longer be seen. This must be a wilful misrepresentation, as he acquired the knowledge of Pocklington's work from the same abstract in which my explanation occurs.

(4) He further says that my knowledge of the literature of the subject must be great when I assume that he has confused "*anthea green*" and "*diatom yellow*," whereas I said distinctly "it would appear, according to Geddes" (see Geddes' paper in NATURE, vol. xxv. p. 303) that he had confused them. I may, however, now observe that his supposition that the colouring matter of the yellow cells of *Anthea* is what he calls a "hepatochromate" can easily be disproved; all that is necessary is to add a little caustic potash or caustic soda to its alcoholic solution when the colouring matter becomes completely altered; for this reason any deductions drawn from Krukenberg's "saponification method" in this case are of little value.

(5) Krukenberg says he had found "chlorophyll-like stuffs" in the livers of animals before I had done so. I am sure this statement is open to question, as his spectra are not accurate representations of what is seen in solutions of *enterochlorophyll.* In most cases only one or two bands are shown by him, and the other proofs brought forward by me are not given in the accompanying text. If his own test for a true chlorophyll be accepted, I can, and hope shortly to, show that animal chlorophyll is a true chlorophyll, and can be obtained in the crystallised state, and the crystals are the same as those obtained by Dr. Hansen, an abstract of whose work will be found in this journal (vol. xxx. p. 224).

(6) It is further suggested that the darkening of the bands in solutions of "echinochrome" (a pigment whose spectrum I have lately described) produced by adding sulphide of ammonium, is caused by precipitation of certain ingredients. This is not the case. The same appearance is produced by stannous chloride and other reducing agents. I have, however, lately succeeded in isolating this pigment, and can confirm my former results. I hope to publish shortly an account of the spectra of its solutions.

(7) Krukenberg makes it appear that I have said that the green gland of the crayfish contains hæmoglobin. I never said so. The statement was this: "In the green gland of one crayfish a band was detected which, I think, was due to reduced *hæmatin*, but it was absent in the second specimen examined." Perhaps Krukenberg thinks that hæmoglobin and hæmatin are the same.

(8) I am made responsible for the statement that the eye of the house-fly contains hæmoglobin; I never said so, nor can I agree with Krukenberg that it gives no band. It gives a band at D, and is not similar to the pigment of the eye of Cephalopods, which he assumes to be the case.

I leave the inferences to be deduced from the above statements to others; but I must protest against Krukenberg's treatment of my work. It is at least satisfactory to know that my experience is not unique, as other English, German, French, and Italian workers receive an equally fair treatment by Dr. Krukenberg.

Wolverhampton, Dec. 23, 1884 C. A. MACMUNN

[1] The papers in which my observations on the subjects referred to were published are:—*Proc. Roy. Soc.*, 1883 (No. 226); *Proc. Birmingham Philos. Soc.*, vol. iii., 1883; and *Brit. Assoc. Reports*, 1883.

Our Future Clocks and Watches

I WOULD suggest, as a modification of "R. B.'s" suggestion in NATURE (p. 80), that the striking of the clocks on the twenty-four system might be varied at each quarter of the day, so as to indicate the time without so much striking. Thus, 1 (a.m.) to 6 might be indicated by the usual method; 7 could be indicated by two strokes, a pause, and one stroke; 8, by two strokes, a pause, and two strokes; and so on to 12; 13, by three strokes, a pause, and one stroke; and so on to 18; 19, by four strokes, a pause, and one stroke; and so on to 24, which being thus indicated by only ten strokes would require less effort to count, and make less noise than by the old system. Dials might be modified in the same way. Instead of twelve there would be only six divisions around the dial, and the quarter of the day could be indicated by a small wheel revolving behind a peephole, or by a third hand (which could be very short) revolving once a day over four divisions or quadrants, marked on the dial near the axis. People, however, would seldom or never need to look at this. Thus would be done away all the objections urged by Harmer. The hour-markings are only conventional signs any way, and it does not make any especial difference in what way the hours are indicated if people would only accustom themselves to the use of the twenty-four hour system in speaking and writing.

H. H. CLAYTON

Ann Arbor, Michigan, December 20, 1884

MODE OF RECKONING TIME AMONGST VARIOUS PEOPLES

THE recent Prime Meridian Conference at Washington has attracted attention to the methods employed at various periods, and amongst peoples in different stages of civilisation, to reckon time. Dr. Robert Schram, on October 24, read an interesting paper on this subject before the Geographical Society of Vienna, in which he dealt chiefly with the Chinese, Hindoos, and the Jews. The three units of measurement given by Nature herself are the rotation of the earth on its own axis, the revolution of the moon in its orbit, and that of the earth around the sun; these are wholly independent of each other, and neither is an aliquot part of the others. But from the earliest times efforts have been made to connect these units; there is the attempt to balance all three, which gives the luni-solar year, or those to connect the day with the course of the sun or of the moon, from which we get the solar or lunar year. In the earliest times the most complicated of these, the luni-solar year, in which it

was sought to connect and equalise all three units, was the one most in use. This is comprehensible when we recollect that now we want to fix single days as far back or in the future, as we wish, and that therefore this form of year appears complicated to us; but in primitive times it was really the most simple form of all, for the sun and moon relieved man of the trouble of reckoning days, and in the months and seasons wrote large on the face of Nature herself the hours and minutes, if we regard the days as seconds. A glance at the heavens or at the surrounding vegetation must have told primitive man the most that he wanted to know of the passage of time, and have supplied the deficiencies of his calendar. How the luni-solar year came direct from Nature herself, and also how it was to be taken as an approximate method only, may be seen in the most ancient form of the Jewish year, which was so regulated that the feast of Passover should be celebrated when, during full moon the barley, which was required as an offering, was ripe, and it must be in the first month of the year, which was then Nisan. Twelve months then were counted from this; but if at the end there was no prospect that the barley would be ripe in fourteen days, a second month, Adar, was simply intercalated, and the new year began with the next new moon. But when an exact and rigid measurement of time is required, this form of year is simply perplexing. The three main types existing down to our own day of the luni-solar year are the Chinese, the Hindoo, and the Jewish years, and each of these is treated by Dr. Schram in turn.

With the Chinese, as in the case of almost every luni-solar year, every month begins with the new moon, and the first month is that in which the sun is in Pisces, the second that in the course of which it enters Aries, and so on. But if the sun in the course of a lunar month does not enter into a new zodiacal sign, it is regarded as an intercalary month, and receives the number of the previous month, with a mark of distinction. In this way months of 29 and 30 days succeed each other, but there is no fixed rule for this succession, nor for the place of the intercalary month of the year, nor for the succession of the intercalary years, and as the commencement of all the months and years have to be astronomically calculated, the whole year is somewhat uncertain and fluctuating, for a few minutes, or even seconds, may alter the beginning of a month by a day, and cause a difference in the intercalation of a month. It is difficult, too, to say according to what tables the astronomical data in the more ancient periods were calculated, so that it would be a matter of much uncertainty to transfer a date into another chronological system, if it were not for the circumstance that the Chinese from the most remote antiquity employed a cycle of 60 days for reckoning the days, much as we employ the week, without regard to the movements of the sun or moon. The uncertainty of the year which prevents the fixing of a precise day two or three years hence has rendered the calendar an indispensable *vade mecum*. The compilation of the calendar has thus become a work of vast importance, which the State has taken on itself and committed to the care of an Imperial mathematical tribunal, presided over by a royal prince. When the work is periodically completed it is presented with great pomp to the members of the Imperial family and to the members of the Government. The years are counted among themselves in two ways, employed simultaneously. The official year is the fourth, fifth, or as the case may be, of the reign of the Emperor, although even this is subject to alteration; while there is also a series of cycles of 60 years each, every individual year having a distinguishing name of its own. These years are named on a system universal in Eastern Asia, which is based on a combination of one name from ten *Kan* or "roots," with one from twelve Chi or "branches." This peculiar method of forming a cycle by the combination of two smaller cycles is found among the Japanese, Manchus, Mongols, and Thibetans, all of whom use the 60-year cycle formed from the cycles of 10 and 12 years; also among the Aztecs a cycle of 52 years, formed from one of 4 and 13 years, is found, which led Humboldt to believe in an infusion of Asiatic ideas in Mexico. The years are more rarely given in a 12-year cycle, each having the name of some animal; this is also universal in Eastern Asia.

The luni-solar year amongst the Hindoos was based on a sidereal solar year, the twelve months of which, though of unequal lengths, were of fixed duration down to the minutest fraction of time. Thus the solar month Chaitra was 30 days, 20 hours, 21 minutes. 2 seconds, and 36 thirds. The day, however, had 60, not 24 hours. The year began with the new moon immediately preceding the commencement of the solar year. But if two lunar months began in the same solar month, the first was intercalated. In case no lunar month fell in the solar month, then that year would lose one of its ordinary months, but at some other part of its course it would have two intercalary months. Every month among the Hindoos has its proper name. The new moons with which they commence are calculated with great exactness and according to inflexible rules, so that it is easier to go back than in the Chinese system. Still there is a difficulty, on account of the various systems employed at different early times. The fact, too, that the day is the thirtieth part of the lunar month, and thus shorter than the natural day, introduces an element of doubt into calculations of this nature. The years are reckoned from 0; the first year of the era is 0, the second 1, the third 2, and so on, so that the number given to any one year is that of the preceding one. The 60-year cycle is also employed, but it is not formed from the combination of two cycles; each year has its own name. It is based on the course of Jupiter and contains five revolutions of that planet; but as the twelfth part of a revolution of Jupiter is only 361 days, 1 hour, 36 minutes, while the sidereal year contains 365 days, 15 hours, 31 minutes, 31 seconds, 6/3rds, a new re-arrangement is from time to time necessary, and a year of the cycle has to be periodically omitted. There are three separate rules for calculating when this is to be done. As eras are employed by the Hindoos for reckoning years, the cycle is of less importance. These eras are themselves divided into cycles of varying lengths. The current era is the Kali Yuga, or Iron Age; 4985 years of it have already passed, so that it is little younger than the era of the creation; but according to Hindoo notions it has still a vast course to run, and it is an age of which not only the beginning but also the end is precisely known. It is to last in all 432,000 years, and the earlier periods run as follows:—

Kali Yuga, or Iron Age	432,000 years
Dvapara Yuga	864,000 ,,
Treta Yuga, or Silver Age	1,296,000 ,,
Krita Yuga, or Golden Age ...	1,728,000 ,,

These four form a so-called Maha Yuga, or Great Age, of 4,320,000 years. Of these Maha Yugas there are 71, giving 306,720,000 years, *plus* a twilight of 1,728,000, give 308,448,000 years, being the length of a patriarchate. There are fourteen of these patriarchates, or 4,318,272,000 years, which, with a dawn of 1,728,000 years, give 4,320,000,000 years, being a kalpa or æon of Hindoo chronology. But the ages extend beyond this, for an æon, or kalpa, is only one day of Brahma; his night is of the same length, and 360 such days and nights form a year of his life, which lasts 100 of these years. The present age is the Kali Yuga of the 28th Great Age of the 7th patriarchate of the first æon of the second half of the life of Brahma, who is therefore 155,521,972,848,985 years old at present. But Brahma's whole life is only a wink of Siva's eye!

Another form of the luni-solar year is that of the Jews.

In its later and more developed form this does not rest on observation or on fluctuating astronomical calculations, but on a comparatively simple cycle, based on a fixed month and year. Everything is settled beforehand: the intercalary month and year are inserted at stated periods. The system is the nineteen-year metonic cycle: nineteen solar years give 235 lunar months, in the course of which the 3, 6, 8, 11, 14, 17, and 19th years are intercalary, a month being inserted between Adar and Nisan. The months are successively 29 and 30 days long, the times of each being settled. But simple as this appears, various circumstances have conspired to render Jewish chronology very complicated. Such are the inclusion of small fractions of time in calculating the new moon for the new year, and the frequent religious precepts dislocating the arrangement for the beginning of the year; so that there are years of 353, 354, 355, as well as those of 383, 384, and 385 days. The years were reckoned regularly from the creation of the world, which is placed on October 7, 3761 B.C.

Having thus discussed the forms of the luni-solar year still in existence, Dr. Schram refers to those formerly in use by various nations. The Greeks also employed the cycle of nineteen lunar years, with seven intercalary months in every cycle, thus approximating to nineteen solar years. The months were of 29 and 30 days, and the years were reckoned by Olympiads of four years each. Subsequently Calippus brought the metonic cycle closer to solar periods by the omission of one day in every 76 years.

Among many peoples the modes of reckoning time do not deserve the name of a system. The Otaheitans used the changes of the moon, and the growth of the bread-fruit; the Makha Indians on Cape Flattery the moon, and the seasons, of which latter they distinguished two, the cold and the warm; the Muysca Indians, according to Humboldt, had 37 lunar months in their cycle, and 20 of these cycles formed a larger one. Where there were no religious festivals connected with the new or the full moon, people gave up the luni-solar year altogether, and adopted the solar year only, confining themselves to bringing day and night into connection with it as far as possible, and paying no regard to the moon's course. It was soon found that the solar year was approximately 365 days in length, and this we find first in the year of the ancient Egyptians. They divided their solar year of 365 days into 12 months, each of 30 days, to which they added 5 supplementary days. The years were counted according to the reigns, and the Canon of Ptolemy is a chronological table giving the commencing years of the various kings. The same form of year is found amongst the Persians, with the difference that the supplementary days were added to the 8th and not to the 12th month. Their months had names, not numbers, and their years were reckoned from the accession of Jezdegird, an era from which the Persians, especially in some parts of India, still count their years. It is remarkable that so inexa_t a year, originating so long ago, should have existed through centuries down to our own day, although its incorrectness was early recognised. The Egyptians, for whom the time of the rising of the Nile, at the ascent of Sirius, was of great importance, noticed soon that the occurrence came later and later in their year, and that if the Dog-star rose one year on New Year's Day, four years later it was the second day, eight years the third, and so on. On this they based the Sothis, or Dog-star period of 1461 Egyptian years, in the course of which Sirius rose successively on every day of the year. Then came the knowledge of the year of 365¼ days, which is tolerably exact, and of this there are several forms of years. In Egypt the change to the more exact reckoning was accomplished in a simple way. The months of 30 days and their names were retained, but to three of them in succession 5 days were added, and every fourth year the supplementary day gave 6 days to 1 month. This form of year is called the Alexandrian, and it is used at present by the Copts in connection with the Diocletian era. This year of 365¼ days was carried to Rome by Cæsar, where the method of counting time was in disorder; and henceforth in Rome the year was of this length, the months consisting of different numbers of days, in place of the Alexandrian supplementary days. This system forms the foundation of our calendar, and is the well-known Julian reform. A peculiar form of the year of 365¼ days was that of the ancient Mexicans. Their solar year consisted of 18 months of 20 days each; at the end of the year 5 supplementary days were added, and at the end of 52 years, 13 more days. The old Icelandic year also was very peculiar. The unit there was the week of 7 days, and in order to make the year an exact number of weeks, there were 12 months of 30 days each, with only 4 supplementary days at the end. Then at the end of 6 or 7 years another week was added, so that the ordinary year consisted of exactly 52 weeks, while the leap year had just 53. The year of 365¼ days was, however, a little too long, and in about 128 years there was an error of 1 day. In the Julian as well as in the Alexandrian system an improvement was found. The former was reformed by Pope Gregory XIII., not so much in the form of the year, as in the method of intercalating. In every year divisible by 100 the intercalary day was to be omitted; but in those divisible by 400 it was to be introduced. Shah Shelal Eddin reformed the Alexandrian system by an ordinance that when the intercalation had taken place every fourth year for 7 or 8 times, the next time it should not take place till 5 years had elapsed. In other words every seventh or eighth leap year was to be the fifth, not the fourth year. Thus there would be 7 leap years in 29, or 8 in 33 years. The last attempt to reform the Alexandrian system was made during the French Revolution, partly with the object of introducing the decimal system into time reckoning, partly also to get rid of all reference to Christianity or any other form of confession. The year which was then introduced was based on the Alexandrian year, but the intercalation was different. The months, consisting of 30 days each, received the names of Vendémiaire, Brumaire, Frimaire, Nivose, &c., and were divided into 3 decades of 10 days each, which took to some extent the places of the weeks. The intercalation was not cyclical, but based on exact astronomical calculations, and it was decreed that the first Vendémiaire should commence with the day on which, according to exact Paris time, the sun entered the autumnal equinox. It is easy to see that this method of intercalating could not exist long without reform, even if there were no independent objections to it, for it has all the defects of the Chinese year. The years were counted from the proclamation of the Republic.

The lunar year is the last portion of his subject treated by Dr. Schram. All that can be said about it occupies but a small space. Here a balancing of the days and of the course of the moon alone is required, the movements of the sun, and the change of the seasons being wholly disregarded. The Turks and Arabs use this year, and indeed it is common all over the Mohammedan world. The year has 12 lunar months; but the Turkish year can hardly be called a year in our sense of the term, with its regular succession and return of the seasons. In the course of 33 years the beginning of this year ranges over the whole of the seasons. If a Turkish festival comes one year in the depth of winter, 16 years later it will be at midsummer. The 12 months have 30 and 29 days: in the leap year the last month has 30 instead of 29 days. In a cycle of 30 years, the leap years are the 2nd, 5th, 10th, 13th, 15th, 18th, 21st, 24th, 26th, and 29th years. The years are counted from the flight of Mohammed from Mecca to Medina.

THE LATE JOHN LAWRENCE SMITH

THE following information relative to Dr. John Lawrence Smith of Louisville, U.S.A., who died on October 12, 1883, in his sixty-fifth year, is abstracted from a sketch of his life and work, prepared by his friend, Prof. Silliman, at the request of the American Academy of Sciences.

John Lawrence Smith was born near Charleston, South Carolina, on December 17, 1818. "Even as a child of four years, and before he could read," says his friend, Dr. Marvin, "he was familiar with the operations of simple arithmetic; at eight he was prepared for the study of algebra, and at thirteen was studying the calculus." At the age of seventeen (1836) he entered the University of Virginia, and for two years devoted himself to the study of chemistry, natural philosophy, and civil engineering. For twelve months after leaving the Univeristy he acted as assistant engineer on the Charleston and Cincinnati railroad, but relinquished the post with a view to the study of medicine. While still a student in Charleston he made known to chemists (1839) the use of potassium chromate as a reagent for distinguishing between the salts of barium and strontium; and in the same year he published a paper on a new method of making permanent artificial magnets by galvanism.

In 1840 Mr. Smith proceeded to his medical degree, submitting as a graduation thesis an essay upon the compound nature of nitrogen. His father being a well-to-do merchant, Mr. Smith was able to continue his medical studies; for this purpose he travelled to Europe, and spent his winters at Paris under Dumas, Orfila, Pouillet, Despretz, Becquerel, Dufrénoy, and Elie de Beaumont, and his summers at Giessen under Liebig. In 1842 appeared his elaborate paper on "The Composition and Products of Distillation of Spermaceti," probably the first extensiue work in organic chemistry undertaken by an American chemist. In 1843 he began medical practice, though chemical research was more congenial to his taste; and, in fact, during the next four years, he found time to contribute important work towards the improvement of analytical methods in chemistry. At this time he also acted as assayer for the State of South Carolina, studying its marls, ores, and cotton-bearing soils. Able reports on these subjects led to his selection by the Secretary of the United States as professional adviser of the Sultan of Turkey in the matter of the introduction into that country of American methods for the culture of cotton. "Finding, on his arrival in Turkey, that an associate proposed to inaugurate the cultivation on a plan doomed to failure, he was about to return to America, when he received from the Turkish Government a commission to explore the mineral resources of the country. He entered at once, with his customary zeal and intelligence, upon the work, and in the four years of his residence in the Sultan's dominions, in spite of many vexatious restrictions, he opened up natural resources which have ever since added an important item to the revenues of the Porte. His memoir on emery (1850) was equally important, both from a scientific and economic stand-point. Before his observations 'On the Geology and Mineralogy of Emery,' made in Asia Minor, little was known of the mode of occurrence of this useful mineral. The island of Naxos had long been almost the only locality, and the supply from this source was limited and the price excessive, and no geologist had found an opportunity of studying the mineral associations of emery or its relations to corundum. Smith's sagacity as an observer, his originality in discussing new methods of examination, his patience and conscientious fidelity in executing his work, are all conspicuous to the student of this memoir. From the study of the mineralogical associations in which he found the emery of Asia Minor, he felt convinced that the search for like associations elsewhere would be rewarded by the discovery of emery or corundum. With this view he addressed Prof. Silliman, requesting him to test the correctness of his observations upon known localities of corundum in the United States. The associate minerals were immediately found and reported. Later on, Smith had the opportunity of seeing the accuracy of his views demonstrated at the emery mine of Chester, Hampden County, Massachusetts, which Dr. Charles T. Jackson had discovered by use of the key of its associate minerals, as suggested by Smith, the locality having been before regarded only as an iron mine."

Weary of the life he led in Turkey, and irritated by the obstacles thrown by the Turkish officials in the way of any real mineralogical exploration of the country, Dr. Smith resigned his appointment in 1850, and returned to America. He married in 1852, and in the same year succeeded to the chemical chair in the University of Virginia, which he retained for one year; it was at this time that he published the method of determining the alkalies in silicates which is now in general use. From 1854 to 1866 he was Professor of Chemistry at Louisville, but finding the restraints of a professorship distasteful, he, in the latter year, resigned the chair, and afterwards devoted his scientific work almost wholly towards the investigation of the chemical nature of meteorites, publishing nearly fifty papers on that subject. Having been successful in collecting illustrations of no less than 250 falls, he was very anxious that the collection should be kept together, and with this view he negotiated its sale for 2000*l*. to Harvard College; the news of the conclusion of the purchase only reached him on the last day of his life. Since his death the sum received from Harvard College has been presented by his widow to the American Academy of Sciences for the institution of a "J. Lawrence Smith medal for researches on meteoric bodies."

"Dr. Smith's personal character possessed a charm which won all who came within the sunshine of his genial nature. His sturdy manliness and integrity was combined with an almost feminine gentleness. During the years of the Civil War, while his affiliations and life-long associations were inseparably united with his native south, he deplored the sad conflict with a spirit bowed as under a personal sorrow; but none heard a word from him which partook of bitterness or animosity, and no shadow passed across the path of his old friendships."

Dr. Smith had no children, but he founded and amply endowed an orphan home in Louisville, his adopted city.

For the last two or three years he was in delicate health, owing to a chronic affection of the liver; and on August 1, 1883, a severe attack of the disease compelled him to take to his bed, from which he never rose again. Without acute suffering he passed peacefully away on Friday, October 12, at three in the afternoon.

By his direction, his funeral was of the most simple character and without an eulogy. His life closed as he had lived, peacefully, with uncomplaining endurance of suffering. His last words were: "Life has been very sweet to me; it comforts me. How I pity those to whom memory brings no pleasure!"

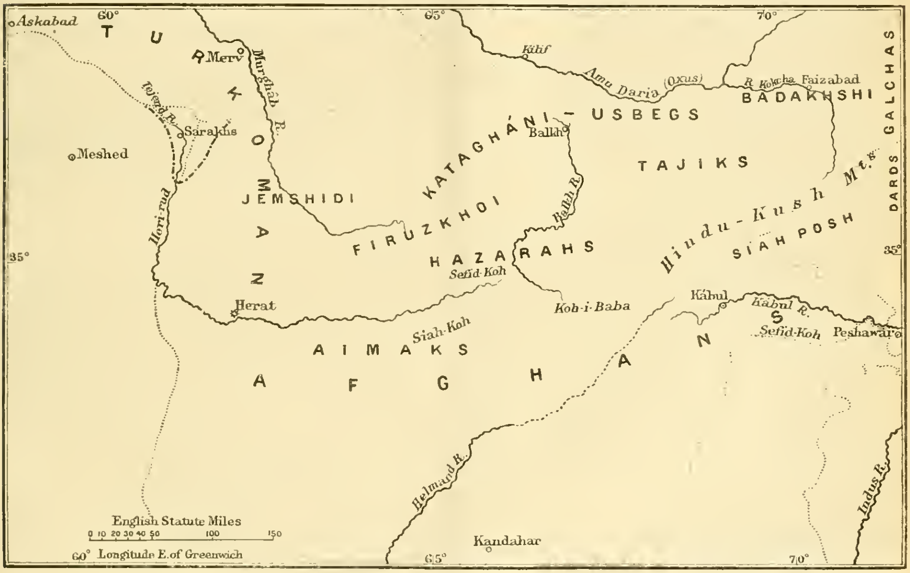
THE NORTH AFGHAN BORDER TRIBES

IN a paper on "Afghan Ethnology," published in NATURE, January 22, 1880, a comprehensive survey was given by this writer of all the varied racial elements in Afghanistan. Here it is proposed to deal exclusively and somewhat more fully with the northern peoples lying along and about the new boundary line proposed to be laid down between the now conterminous Anglo-Indian and Russian empires. Were the importance of ethnological studies understood or recognised by British statesmen, it would be needless to insist upon an accurate knowledge of the tribal relations in this border-land

before determining the future line of demarcation between the two States. As matters stand, nothing can be done beyond supplying a few authentic data, which, if not too late, may possibly help our Boundary Commissioners to appreciate the gravity of the situation.

Politicians of eminence have in recent times spoken flippantly of a great and consolidated Afghan people, one in origin, speech, usages, national aspirations, in friendly alliance with the British *ráj*, destined to constitute a formidable bulwark of the Indian Empire against the further encroachments of the northern Colossus. Those who have conjured up this pleasant vision, and shaped their policy in the belief of its realisation in our days, are doubtless well meaning persons; but they are not practical men of business, dwellers rather in dreamland than sober inhabitants of this planet. Afghanistan is not the home of one, but of many peoples, differing widely in race, language, customs, in some cases even in religion and political institutions; nor are the materials at hand by which these heterogeneous fragments could be welded into a single body politic for many generations to come.

A mere glance at the accompanying sketch map will suffice to show that the Afghan race proper, since the death of Nadir Shah (1747) heir to the former Persian masters of the land, nowhere even approaches the northern frontiers, except in the Herat district towards the north-west. Notwithstanding their great elevation, the mountain ranges stretching from the Hindu-Kush, through the Koh-i-Baba and parallel Safed-Koh and Siah-Koh chains westwards to Khorasán, constitute neither an ethnical, a political, nor even a complete physical parting line between the Afghan plateau and the Turkestan lowlands. The Hindu-Kush itself doubtless forms a distinct "divide" for the waters flowing north to the Oxus, south to the Indus basin. Further west, also, all the head streams of the Murgh-áb, or River of Merv, have their



sources on the northern slope of the Safed-Koh, probably the Paropamisus of the ancients. But here the mountain barrier is completely pierced by the Heri-rud, which takes its rise south of the Koh-i-Baba, and, after flowing a long way west between the Safed-Koh and the Siah-Koh, trends northwards beyond Herat to the Turkestan steppe. Politically, also, the rampart is broken all along the line, both slopes from Kashmir to Persia being claimed and hitherto recognised as integral parts of Afghan territory. Thus the whole of Afghan Turkestán, of Badakhshán, and the more remote north-eastern provinces of Wakhán and Shugnán, are comprised within the Aralo-Caspian hydrographic system.

A clear idea of these geographical features is necessary to a right understanding of the racial conditions in this extremely intricate ethnological region. From before the dawn of history constituting a natural parting line between Irán and Turán, it has, nevertheless, been so repeatedly crossed and re-crossed by the contending floods of migration and conquest, advancing now from the north, now from the south, that throughout the historic period it appears to have always been occupied by peoples both of Mongolic and of Caucasic stock. At present the former are found mainly in the western section, between the meridians of Kábul and Herat, the latter thence eastwards to the Pamir and Indus, each on both slopes of the Iranian escarpment between the 34° and 40° parallels. Of the two the Caucasic appears to be the aboriginal, the Mongolic the intruding, element; and by many ethnologists the upland valleys of the "Indian Caucasus" are regarded, if not as the cradle, at least as the centre of dispersion of the Aryan branch of the Caucasic group. Hence, those members of the Aryan family still occupying both slopes of the Hindu-Kush are supposed to be found, so to say, *in situ*, that is, in undisturbed possession of their primeval homes from the first. Such are, on the south side, the so-called SIAH-POSH, or SIAH-POSH KAFIRS ("Black-clad Infidels"), and further

east the numerous communities often collectively known as DARDS; on the north side the BADAKHSHI, WAKHI, and SHUGNÁNI, to whom, with the other kindred highlanders of Roshán, Darwáz, and Karateghin, beyond the Oxus, Ch. de Ujfalvy has applied the collective term GALCHA. That all are fundamentally of one stock there can be no doubt, although much uncertainty prevails regarding their position in the Aryan family.

The northern group (Badakhshi, Wakhi, Shugnáni) have long been brought within the sphere of Iranian culture. Some are Parsiván, that is, Parsi-zabán, or "Persian-tongued"; others, especially in Wakhan, still retain much of their primitive speech, which appears to be intermediate between the Indic and Iranic members of the Aryan family. But all are at least nominal Mohammedans of the Sunni sect, and recognise the supremacy of the Amir of Kábul. In view of future political intrigue on this extreme north-east frontier, it will be desirable to bear in mind the close affinity and common sympathies of all these communities on both sides of the Upper Oxus.

Even more interesting, and in some respects more important, is the southern group of Siah-Posh Kafirs, who occupy the upland valleys between Kohistán and the Swati district, and even visit the northern pastures west of the Dora Pass, crossing the Hindu-Kush at an altitude of some 16,000 feet. In these mountain fastnesses they have hitherto succeeded in preserving intact not only their primitive speech, usages, and religion, but even their political independence. Although included within the limits of the Amir's possessions, no Afghan ventures to penetrate into their territory, which till quite recently was almost a *terra incognita*. By Major Tanner, and the few other Europeans by whom they have been visited, they are described as of a pure Caucasic type, with regular features, blue and dark eyes, hair varying from brown to black, and altogether the most European in appearance of all Asiatic peoples. With the British rulers of India they claim kindred, trace their descent from Alexander the Great, differ from other Asiatics in the use of chairs and tables, and speak a pure Aryan dialect, showing marked affinities to Sanskrit. Some few in the extreme south and west have become assimilated in speech and religion to their Afghan neighbours, and these Safi and Nemchi, as they are called, serve as the medium of communication between the two races. For obvious reasons the masters of India should cultivate the friendship and alliance of the Siah-Posh highlanders, who, from the name of their most powerful *gali*, or tribe, sometimes take the collective name of Kamoji.

The south-western slopes of the Hindu-Kush north of Kábul are held by several little known tribes vaguely known as KOHISTÁNI, or "Hill men." They occupy the whole district between Kafiristán and the Koh-i-Baba. They are mainly Tajiks, that is, Iranians, probably descended of Persian settlers in pre-Mohammedan times, and still speak a rude Persian dialect. Although now Mohammedans of the Sunni sect, they appear to be an unruly people, owing a reluctant allegiance to the Amir, in this and some other respects differing from the other Tajiks found dispersed in settled communities elsewhere in Afghanistan and throughout the whole of Central Asia. The name, referred to the root *táj* = *crown*, is supposed to mean "crowned," indicating the imperial race that once held sway from the Bosporus to the Indus. But the sceptre has long passed from Irán to Turán even in Persia itself, where the reigning dynasty belongs to the Qajár tribe, of Turkoman stock.

As already stated, both slopes of the North Afghan highlands are in almost exclusive possession of Mongolic peoples from the Koh-i-Baba to Herat, east and west, and from Afghan Turkestan southwards to the Ghor uplands. Here both branches of the Mongolo-Tatar group are represented, the Mongols proper by the HAZARAHS and the AIMAKS, the Tatars by the TURKOMANS and the KATAGHÁNI USBEGS. With the Hazarahs are sometimes grouped the JEMSHÍDIS and FIRUZ-KHOI of the province of Herat. But both of these numerous communities appear to be fundamentally of Iranian stock, although the type has to some extent been modified by contact with the surrounding Mongolo-Tatar tribes.

Thus it appears that, as above remarked, the Afghans proper nowhere occupy any territory along their northern frontier, but, except at Herat, have everywhere been driven into the interior of the plateau by the intruding Central Asiatic races. It is further to be noted that although they hold the Usbegs of the Tirband-i-Turkestán escarpment and of the Turkestán lowlands in military subjection, they have hitherto failed to reduce either the Aimaks of the Ghor district or the Hazarahs of the Koh-i-Baba and Safed-Koh ranges. The direct route from Herat to Kábul through this region has not only never yet been traversed by any European explorer, but is absolutely inaccessible to the Afghans themselves. Hence it is that the military and trade route between these two points is deflected a long way southwards to the Helmand basin and to Kandahar, whence it laboriously creeps up through the Ghazni highlands to the Kábul valley.[1] Hence also the vast strategic importance of such places as Kandahar and Girishk on the Helmand, which depends, not, as is generally supposed, so much on the lie of the land, as on the ethnical conditions of its inhabitants. The future masters of the Aimak and Hazarah tribes will not only secure the rich prize of the Ghor region, with its untouched mines of gold, silver, copper, lead, iron, coal, sulphur, rubies, and emeralds, but will also command the direct and natural route from Herat to the Indus, *viâ* Kábul and Pesháwar.

Meantime, these Aimaks and Hazarahs, neglected by our statesmen, continue to interest our men of science alone. Their flat features, tawny complexion, scant beard, oblique eyes, and prominent zygomatic arches, betray their common Mongolic descent, while the somewhat rude Persian dialect generally spoken by both implies long contact in their new homes with Iranian culture. Both are also Mohammedans; the Aimaks of the Sunni, the Hazarahs of the Shiah sect, in this respect differing from all other Mongolian tribes, who are exclusively Buddhists. Another proof of Persian influence is the settled life of the Hazarahs,[2] who have long ceased to be nomads, and now occupy permanent villages of small thatched houses. Of late years they have begun to migrate towards India, where they find employment on the public works.

The Aimaks, or Char Aimaks, that is "Four Hordes," so named from their four main divisions, occupy, besides the Ghor country, extensive tracts on the northern slope of the border ranges, on the hills encircling Herat, and beyond the frontier in Khorasán. Some communities in the Herat district have preserved their mother-tongue, and their chief tribe even still bears the Mongol name of Kipchak. They also retain the old *urdu*, or tents made of felt or skins, and usually grouped round a central tower or stronghold occupied by the chief. They are described as altogether more savage and ferocious than their Hazarah neighbours, and are even said to drink the blood of the slain in battle (Elphinstone).

With the fall of Merv all the hitherto independent Turkoman tribes passed under the sceptre of the "White Czar," except the SARIKS and the SALORS. Soon after that event the Sariks of the Merv oasis gave in their submission to the number of about 10,000 families. When that district was invaded in 1860 by the Tekkés, the Salors, its original masters, withdrew higher up the Murgháb valley, where they are still found within and about the Afghan frontier, on the route between Merv and

[1] The direct route is little over 360 miles, the detour by Kandahar about 550.

[2] Probably so named from the Persian *hazár* = a thousand, in allusion to their numerous tribal subdivisions.

Herat. They do not recognise the authority of the Amir of Kábul, and should the Czar, who is about to assume the title of "Emperor of Central Asia," claim the allegiance of this outlying Central Asiatic tribe, here will be a fruitful source of future complications. Their submission would at once advance the Russian frontier far into Afghan territory and up the Murgháb valley to within easy distance of Herat from the north. The route in this direction is well known, and constantly traversed by traders from Khiva, Bokhara, and Samarkand. It appears to present no greater difficulties than the more westerly route crossing the Barkhut ridge recently surveyed by Lessar.

There remain to be mentioned the KATAGHÁNI USBEGS, who form the bulk of the population in Afghan Turkestán. They belong to the same ethnical group as the Usbegs of the Khanates, and have even some settlements in Bokhara beyond the Oxus. They are mostly agriculturists and traders, Sunnite Mohammedans of pure Turki speech, and bear with reluctance the hard yoke of their Afghan masters. Their sympathies are entirely with their northern kinsmen, and as the country (Kunduz, Balkh, Maimene) belongs geographically to the Aralo-Caspian basin, it is difficult to see how further rectifications of frontier can ultimately be prevented in this direction. Exponents of advanced public opinion in Russia already openly claim the whole of this region to the crest of the Hindu-Kush as properly belonging to the ruler of Central Asia, and their arguments are largely based on ethnological grounds.

Table of the North Afghan Border Tribes

CAUCASIC STOCK

	Tribe	*Locality*	*Population* [1]
Galchas	Siah-Posh	Kafiristán	150,000
	Badakhshi	Badakhshán	160,000
	Wakhi	Wakhán	3,000
	Shugnáni	Shugnán	25,000
Iranians	Kohistáni	Kohistán	?
	Firuz-Khoi... ...	Prov. Herat, Murgháb Valley	30,000 tents
	Jemshidi	Prov. Herat, Khushk Valley	12,000 families
	Tajiks...	Herat, Balkh, &c.	200,000 ?
	Afghans	Herat	100,000 ?

MONGOLIC STOCK

	Tribe	*Locality*	*Population*
Mongols	Hazarahs	Hazaraját ... ... Koh-i-Baba, Safed-Koh ...	300,000
	Aimaks	Ghor, Herat, Khorasán ...	350,000
Tatars	Salor Turkomans	About Martshag, Murgháb Valley	30,000
	Katagháni Usbegs	Afghan Turkestán, Bokhara	600,000

A. H. KEANE

[1] Population mostly conjectural.

ANTHROPOMETRIC PER-CENTILES

I SEND the following Table, partly to exemplify what I trust will be found a convenient development of a statistical method that I have long advocated, and partly for its intrinsic value, whatever that may be. It will at all events interest those of the 9337 persons measured in my Anthropometric Laboratory at the late International Health Exhibition, who may wish to discover their rank among the rest.

Its meaning is plain, and will be understood by the help of a single example, for which I will take the line referring to Strength of Squeeze among males. We see that a discussion was made of 519 measurements in that respect, of men whose ages ranged between 23 and 26; that 95 per cent. of them were able to exert a squeeze with their strongest hand (the squeeze was measured by a spring dynamometer) that surpassed 67 lbs. of pressure; that 90 per cent. could exert one that surpassed 71; 80 per cent. one that surpassed 76; and so on. The value which 50 per cent. exceeded, and 50 per cent. fell short of, is the Median Value, or the 50th per-centile, and this is practically the same as the Mean Value; its amount is 85 lbs. This line of the Table consequently presents an exact and very complete account of the distribution of strength in one respect among the middle 90 per cent. of any group of males of the tabular ages similar to those who were measured at the laboratory. The 5 per cent. lowest and the 5 per cent. highest cannot be derived directly from it, but their values may be approximately inferred from the run of the tabular figures, supplemented by such deductions as the Law of Error may encourage us to draw. Those who wish to apply this law will note that the probable error is half the difference between the 25th and the 75th per-centile, which can easily be found by interpolation, and they will draw the per-centiles that correspond respectively to the median value *minus* twice, three times, and three-and-a-half times the probable error, at the graduations 8·7, 2·4, 0·8, and those that correspond to the median value *plus* those amounts, at the graduations 91·3, 97·6, and 99·2. The Table is a mere statement of observed fact; there is no theory whatever involved in its construction, beyond simple interpolations between values that differ little from one another and which have been found to run in very regular series.

It may be used in many ways. Suppose, for example, that a man of the tabular age, viz. above 23 and under 26, and who could exert a squeeze of 80 lbs., desired to know his rank among the rest, the Table tells him at once that his strength in this respect certainly exceeds that of 30 per cent. of those who were measured, because if it had been only 79 lbs. it would have done so. It also tells him that his strength does not exceed that of 40 per cent. of the rest, since it would have required a pressure of 82 lbs. to have done this. He therefore ranks between the 30th and the 40th per-centile, and a very simple mental sum in proportion shows his place to be about the 33rd or 34th in a class of 100.

The Table exhibits in a very striking way the differences between the two sexes. The 5th male per-centile of strength of squeeze is equal to the 90th female per-centile, which is nearly but not quite the same as saying that the man who ranks 5th from the bottom of a class of 100 males would rank 10th from the top in a class of 100 females. The small difference between the two forms of expression will be explained further on. If the male per-centiles of strength of squeeze are plotted on ruled paper, beginning with the lowest, and if the female per-centiles are plotted on the same paper, beginning with the highest, the curves joining their respective tops will be found to intersect at the 7th per-centile, which is the value that 7 of the females and 93 of the males just surpass. Therefore, if we wished to select the 100 strongest individuals out of two groups, one consisting of 100 males chosen at random, and the other of 100 females, we should take the 100 males and draft out the 7 weakest of them, and draft in the 7 strongest females. Very powerful women exist, but happily perhaps for the repose of the other sex, such gifted women are rare. Out of 1657 adult females of various ages measured at the laboratory, the strongest could only exert a squeeze of 86 lbs. or about that of a medium man. The population of England hardly contains enough material to form even a few regiments of efficient Amazons.

The various measurements of males surpass those of females in very different degrees, but in nearly every particular. A convenient way of comparing them in each case is that which I have just adopted, of finding the per-centile which has the same value when reckoned from the lower end of the male series, and from the higher end of the female series. When this has been done, the position of the

ANTHROPOMETRIC PER-CENTILES

Values surpassed, and Values unreached, by various percentages of the persons measured at the Anthropometric Laboratory in the late International Health Exhibition

(*The value that is unreached by n per cent. of any large group of measurements, and surpassed by* 100–*n of them, is called its nth per-centile*)

Subject of measurement	Age	Unit of measurement	Sex	No. of persons in the group	Values surpassed by per-cents as below: 95	90	80	70	60	50	40	30	20	10	5

			F.	433	10	12	16	19	22	24	26	27	29	31	32

per-centiles arranged in order of their magnitude are as follows:—Pull, 4; Squeeze, 7; Breathing capacity, 10; Height, 14; Weight, 26; Swiftness of blow, 26; Keenness of sight, 37. We conclude from them that the female differs from the male more conspicuously in strength than in any other particular, and therefore that the commonly used epithet of "the weaker sex," is peculiarly appropriate.

The Table was constructed as follows:—I had groups of appropriate cases extracted for me from the duplicate records by Mr. J. Henry Young, of the General Register Office. I did not care to exhaust the records, but requested him to take as many as seemed in each case to be sufficient to give a trustworthy result for these and other purposes to which I desired to apply them. The precise number was determined by accidental matters of detail that in no way implied a selection of the measurements. The summarised form in which I finally took them in hand, is shown in the two upper lines of the following specimen:—

Height, Sitting, of Female Adults, Aged 23–50, *in inches*

29–	30–	31–	32–	33–	34–	35–	36–	37–	
2	8	52	116	226	227	108	31	5	Total 775
2	10	62	178	404	631	739	770	775	Abscissæ 0 to 775
30	31	32	33	34	35	36	37	38	Corresponding Ordinates

The meaning of the two upper lines is that in a total of 775 observations there were 2 cases measuring 29 and under 30 inches, 8 cases measuring 30 and under 31 inches, and so on. The third line contains the sums of the entries in the second line reckoned from the beginning, and is to be read as follows:—2 cases under 30 inches, 10 cases (= 2 + 8) under 31 inches, 62 cases (= 2 + 8 + 52) under 32 inches, and so on.

I plotted these 775 cases on French "sectional" paper, which is procurable in long and inexpensive rolls, ruled crossways by lines 1 millimetre apart. I counted the first line as 0° and the 776th as 775°. Supposing the measurements to have been plotted in the order of their magnitude, in succession between these lines, the first would stand between 0° and 1°, the second between 1° and 2°, and so on. Now we see from the Table that the second measurement was just short of 30 inches, consequently the third measurement was presumably just beyond it, therefore the abscissa whose value is 2°, and which separates the second from the third measurement, may fairly be taken to represent the abscissa of the ordinate that is equal to 30 inches exactly. Similarly, the abscissa whose value is 10° divides the measurement that is just under 31 inches from that which is presumably just above it, and may be taken as the abscissa to that ordinate whose precise value is 31°, and so on for the rest. The fourth line of the Table gives the ordinates thus determined for the abscissæ whose values are entered above them in the third line. I dotted the values of these ordinates in their right places on the sectional paper, and joined the dots with a line, which in every case, except the breathing capacity, fell into a strikingly regular curve. (I cannot account for this one partial exception, save on the supposition of the somewhat irre-

gular mixture of town and country folk, and of sedentary and active professions among the persons measured, but I have not yet verified this surmise.) Per-centiles were then drawn to the curve corresponding to abscissæ that were respectively 5 per cent., 10 per cent., 20 per cent., &c., of the length of the base line. As the length of the base-line was 275, these per-centiles stood at the graduations $13^{\circ}\cdot 8$, $27^{\circ}\cdot 5$, $55^{\circ}\cdot 0$, &c. Their values, as read off on the sectional paper, are those which I have given in the Table.

It will be understood after a little reflection that the 9th rank in a row of 10, the 90th rank in a row of 100, and the 900th rank in a row of 1000, are not identical, and that none of them are identical with the 90th percentile. There must always be the difference of one half-place between the post which each person occupies in a row of n individuals, numbered from 1 to n, and that of the corresponding graduations of the base on which they stand, and which bear the same nominal value, because the graduations are numbered from 0 to n and begin at a point one half-place short of the first man, and end at one half-place beyond the last man. Consequently the graduations corresponding to the posts of the 9th, 90th, and 900th man in the above example, refer to the distance of those posts from the beginning at 0 of their several base lines, and those distances are related to the lengths of the base lines in the proportions of 8·5 : 10, 89·5 : 100, and 899·5 : 1000, which when reckoned in per-cents of the several base lines are 85, 89·5, and 89·95 respectively. The larger the number of places in the series, the more insignificant does this half-place become. Moreover, the intrusion of each fresh observation into the series separates its neighbours by almost double that amount, and propagates a disturbance that reaches to either end, though it is diminished to almost nothing by the time it has arrived there. We may therefore ignore the existence of this theoretically troublesome half-place in our ordinary statistical work.

There is a latent source of error that might affect such statistics as these, as well as many others that are drawn up in the usual way, which has not, so far as I know, been recognised, and deserves attention. It is due to uncertainty as to the precise meaning of such headings as 30-, 31-, &c. If the measurements, no matter whether they were made carefully or carelessly, are read off from the instruments with great nicety, then a reading such as 30·99 would fall in the column 30-, and the mean of all the entries in such a column might fairly be referred to a mean value of 30·5.

But if the instruments are roughly read, say, to the nearest half inch, the reading of a real instrumental value of 30·99, and even that of a real value of 30·76, would both be entered in the column 31-. The column 30- would then contain measurements whose real instrumental values ranged between 29·75 and 30·75, and the column 31- would contain those that ranged between 30·75 and 31·75; consequently, the means of all the entries in those columns respectively should be referred, not to 30·5 and 31·5, but to 30·25 and to 31·25. An error of a quarter of an inch in the final results might easily be occasioned by the neglect to note the degree of minuteness with which the instruments were read, and I strongly suspect that many statistical tables are affected by this generally unrecognised cause of error. The measurements at my laboratory were read to the nearest tenth of an inch and to a fraction of a pound, so I can afford to disregard this consideration. There was, however, a slight bias in favour of entering round numbers, which should have been, but were not (because I neglected to give the necessary instructions), rateably divided between the columns on either side.

A fuller description of the results of the measurements at the laboratory will appear next February or March in the forthcoming number of the *Journal* of the Anthropological Institute, at which place the original data will ultimately be deposited.

FRANCIS GALTON

NOTES

IT having become known to some of the friends of the late Mr. Henry Watts, the well-known chemist, whose death occurred very suddenly on the 30th of last June, that his widow and family are in very straitened circumstances, an informal meeting was recently held at the Royal Institution. Those present resolved to form themselves into a committee, with power to add to their number, in order to collect a fund for the benefit of Mrs. Watts and those of her children who are not of an age to provide for their own support. Dr. Atkinson consented to act as secretary, and Dr. Perkin, President of the Chemical Society, as treasurer. Among the names on the committee are those of Sir F. A. Abel, Prof. H. E. Armstrong, Mr. William Crookes, Dr. Warren De La Rue, Prof. James Dewar, Prof. G. C. Foster, Dr. J. H. Gladstone, Prof. A. G. V. Harcourt, Dr. Hugo Müller, Dr. William Odling, Dr. W. H. Perkin, Dr. B. W. Richardson, Prof. W. Chandler Roberts, Sir H. E. Roscoe, Dr. W. J. Russell and Prof. A. W. Williamson. Mr. Watts's public labours for the advancement of chemical science may be said to have begun with the translation of Gmelin's "Handbook of Chemistry," the admirable English edition of which was prepared and edited for the Cavendish Society by him. This work occupies eighteen large octavo volumes, of which the first appeared in 1849, and the last in 1871. A work scarcely, if at all, inferior to this in magnitude, and one which has perhaps been of even greater service to English chemists, both scientific and industrial, is Watts's great "Dictionary of Chemistry," which appeared from 1863 to 1881, in eight volumes, containing altogether nearly 9700 pages. Mr. Watts also edited and largely added to the second volume of the late Prof. Graham's "Elements of Chemistry," published in 1858; he prepared several editions of Fownes's well-known "Manual of Chemistry," which he almost entirely re-wrote and made into virtually a new work; and in conjunction with Mr. Ronalds and Dr. Richardson, he prepared for Messrs. Baillière an elaborate treatise on chemical technology. Up to the time of his death, and for about thirty years previously, Mr. Watts was editor of the *Journal* of the Chemical Society, and in this capacity, as well as in that of librarian to the Chemical Society, he became personally known to and gained the friendship of very many among the Fellows of the Society. But although Mr. Watts's life was one of unremitting labour, the money return for his work was barely sufficient to enable him to provide for the daily wants of a delicate wife and a numerous family. It was not possible for him to provide for their future needs. But if he could not leave behind him pecuniary resources, he accumulated esteem and affection among all who knew him, which, it is confidently hoped, will prove a valuable legacy for those who were dependent on him. The facts of the case show that there is great need of whatever practical proof of their regard for him and appreciation of his labours Mr. Watts's friends, and English chemists generally, may be willing to make. For many years Mrs. Watts has been in ill-health, so that she cannot do anything for her own support and that of her family. One son is a permanent invalid, and the four youngest children have still to be educated. A considerable expenditure is therefore unavoidable for a good many years to come, if the children are to have a fair chance of a start in life. A considerable sum has already been promised in the way of subscriptions, but much more will have to be done in order that any substantial benefit may accrue to Mrs. Watts and her young family. Subscriptions will be received and acknowledged

by the Secretary, Dr. Edmund Atkinson, Portesbery Hill, Camberley, Surrey, or by the Treasurer, Dr. W. H. Perkin, the Chestnuts, Sudbury, Harrow.

M. MILNE EDWARDS has been nominated by the French Government Grand Officer of the Legion d'Honneur.

LECTURES in connection with the London Society for the Extension of University Teaching have been going on in Whitechapel now for more than six years. The number of tickets sold for the lectures during this period has been close upon 2000, and the ticket-holders have been nearly all artisans. The reports of the examiners, appointed by the Universities' Board, have shown that many of those attending the lectures are real students—a conclusion which is also borne out by the fact that the same subjects have been studied for several years in succession. It has been felt that a good reference library and reading room would be a great help to the existing students, as well as a means of attracting others. An opportunity for providing these advantages is now afforded in the "Universities' Settlement" in Toynbee Hall, where the lectures will in future be given, and a reading room be opened to the students. The Committee desire to stock this room with a good reference library—especially in the subjects of history, political economy, physics, and physiology—and will be very grateful for any assistance in this attempt to further higher education among working men and women in East London. Any one willing to help, either with books or with money, is requested to communicate either with E. T. Cook, 22, Albemarle Street, W. (Sec. London Society for the Extension of University Teaching), or Bolton King, 28, Commercial Street, E. (Hon. Sec. Whitechapel Local Committee).

THE mean-time clocks at the Royal Observatory, Greenwich, were put forward twelve hours a little before midnight of December 31, in order that the commencement of the civil day and the astronomical day might be identical from January 1, 1885. The public clock near the entrance to the Observatory will thus indicate the hours as recommended by the Washington Conference—*i.e.* reckoning from 0h. to 24h., starting from midnight. As the Greenwich observations for 1885 will not be printed until 1886, the proposed method can be tried for a year before the necessity of deciding on its adoption will arise. In writing to the Rev. T. E. Espin, President of the Liverpool Astronomical Society, the Astronomer-Royal says:—"The change that we propose to make at Greenwich is for the present provisional only, as it appears essential that it should be generally accepted by astronomers before it is introduced into any published observations I am very anxious to avoid the confusion which would result from two systems of reckoning time being in use among astronomers. But as regards the ordinary public, it seems to me clear that for civil reckoning the day must commence at midnight, and in order to assist in familiarising the public with the reckoning from 0h. to 24h., I propose on January 1 to alter our public clock (which is numbered from 0h. to 24h.) by 12h., so that it will show civil reckoning instead of the old astronomical reckoning."

CHEMISTS will regret to learn that Dr. Edward Divers, Principal of the Imperial College of Engineering, Tokio, Japan, has met with a very serious accident, which it is feared will result in the loss of one of his eyes. He is understood to have been engaged in work in connection with the theory of acids, when a bottle, supposed to contain terchloride of phosphorus, exploded, causing him very severe injuries. Dr. Divers is well known as the author of many valuable chemical papers read before the Royal and other scientific societies.

MR. ALFRED TYLOR, F.G.S., who died on December 31 last, will be remembered as a promoter of technical education at a time when its vital importance was little recognised, and the English manufacturing mind was generally set against it. He was intimately associated with Dr. von Steinbeis, whose energy in this direction did so much to give the little kingdom of Wurtemburg its industrial prominence in Germany. Mr. Tylor's work, "Education and Manufactures," arising out of his Jury Report on Metal Work at the Exhibition of 1862, was translated into German under the title "Industrie und Schule" (Stuttgart, 1865), and also appeared in Swedish. Mr. Tylor sat for some years on the Council of the Geological Society. His geological papers relate principally to the flow of rivers as connected with the erosion of valleys and the deposit of gravel-beds; they contain much systematised information, for instance, as to the mechanical action of the Mississippi and the Ganges. It is well known that his study of river-valleys and drift-gravels led him to the hypothesis of a post-glacial time of enormous rainfall, which he called the "pluvial period." The term, though not generally accepted, is found of use, to judge from its not unfrequent appearance in geological works.

THE death is announced, at the age of seventy-four years, of Dr. Andrew Findlater, for so many years connected with the editorial department of Messrs. W. and R. Chambers. Dr. Findlater wrote several of the scientific volumes in Chambers's well-known "Educational Course," and edited a revised edition of the "Information for the People." But his most important undertaking was the editing of "Chambers's Encyclopædia," the scientific articles in which hold so high a place, mainly through Dr. Findlater's knowledge, discernment, and tact in obtaining the right men to act as contributors. Dr. Findlater was offered the editorship of the new edition of the "Encylopædia Britannica," but was induced to decline it.

WE read in the German papers that the Greek Government has offered to supply the marble, as it did in the case of Lord Byron's monument in England, for a national monument to be erected to Wilhelm Müller, the father of Prof. Max Müller, in his native town of Dessau. Wilhelm Müller is best known as the poet of the "Müller-lieder," beautifully set to music by Schubert. But the Greek Government, in the name of the Greek nation, wished to express its recognition of the great services rendered to the cause of Greek independence by Wilhelm Müller, "the Philhellenic Tyrtæus," whose "Griechenlieder" belong to the classical literature of Germany. Committees have been formed in Germany, Italy, Greece, and America. The English committee consists of Mrs. Jenny Lind-Goldschmidt, Sir Theodore Martin, Sir Robert Morier, Sir George Grove, J. A. Froude, and Prof. Buchheim. Subscriptions are received by Messrs. Williams and Norgate, 14, Henrietta Street, W.C.

BAVARIAN papers report the death, after a short illness, of Dr. Philip von Jolly, Professor of Mathematical and Experimental Physics in the University of Munich, in the seventy-fifth year of his age.

A NEW association has been established among the students of the University of Paris. The first step of this institution has been the organisation of a public manifestation in honour of M. Chevreul, the director of the Museum, who is just completing his 100th year. He is the first French academician who has reached this advanced age since the death of Fontenelle, who died about 1750, a few days before completing his century. A little before his death Fontenelle was heard to say to one of his friends asking if he complained of some illness, "I have no suffering, but I am feeling merely an increased difficulty of living."

WE learn from *Science* that the "cold-wave flag," whose use has been inaugurated by the U.S. Signal Service during the past autumn, is intended to be displayed not only at the regular

stations of the Signal Service, but also at as many railway-stations and post-offices as possible, in order to spread the widest notice of the coming change of weather. The service cannot at present undertake to provide the flags or to pay for special telegrams to numerous local display-stations; but the cost of the flags (white, six feet square, with a two-foot black square in centre) is moderate, and can easily be borne by those interested in securing early indications of falling temperature; and in several parts of the country the telegrams are sent to all the stations on certain railroads that co-operate with the Signal Service, and thus promptly distribute weather forecasts to the towns along their routes. It is probable that the coming year will see a considerable extension of this kind of weather service.

M. Jamin, the Perpetual Secretary of the Paris Academy of Sciences, has published, in the January issue of *Revue des Deux Mondes*, the essay on balloons, which we announced a few weeks ago. The academician takes a very moderate view of the success of the Meudon and Point du Jour experiments.

The terrestrial disturbance in Southern Spain, which began with violent earthquake shocks on Christmas night, still continues, and other earthquakes are reported from Austria and Italy. From Vienna information comes of repeated shocks on the 4th inst. in the hot-spring district of Southern Styria, during which some slight damage was done, while on the afternoon of the same day a shock, perhaps of the same earthquake, was felt at Susa, near Mont Cenis, and one of greater force on the morning of the following day (January 5) at Velletri, near Rome. The seismic instruments at the observatory in Rome and at Rocca di Papa showed unusual activity on the 5th and previous days, especially at midday, and at night the mineral springs in the Island of Ischia have risen in temperature. It would thus appear that the present is a period of unusual seismic disturbance throughout Southern Europe. In Spain no day has passed since the 25th ult. without one or more severe shocks in the disturbed area. On the 31st ult. the tenth violent shock in a week occurred in Granada—the people left their houses for the night—and up to that date 10,000 people had left the town altogether. On the same day and on the 1st inst. shocks continued at Jaen, Torrox, Malaga, Benamargoza, and Velez Malaga. At Torrox buildings were thrown down, and the town has been wholly abandoned. At Nerja the church was damaged, and at Arenas del Rey 500 persons were either killed or injured. On the 1st inst. and the morning of the 2nd fresh shocks were felt at Nerja, Algarrobo, Granada, and Malaga. A number of towns and villages are reported completely destroyed and deserted. On the 2nd shocks were felt along the Mediterranean coast of Granada and Malaga. Up to noon on the 3rd inst., according to official statistics, 673 bodies were recovered from the ruins of towns in the province of Granada alone. On that day the shocks were renewed in Loja, Alhama, Jaen, and Velez Malaga, fissures being made in the ground. The town of Alhama, which has suffered most severely of all, is composed of two parts, the upper and lower. During the earthquake on Christmas night the upper town, situated on the side of a valley, fell into the lower portion. Over 1500 houses were destroyed, and more than 300 dead were recovered up to the 4th inst. It is calculated that 10,000 head of cattle were killed. Besides this, five churches, five convents and hospitals, the town-hall, the prisons, clubs, and theatre were destroyed, and 7000 people rendered homeless. On the 5th a sharp shock occurred at Granada a few minutes after 6 in the evening, and some slight shocks were felt at Malaga.

At the Royal Institution, Prof. H. N. Moseley will, on Tuesday next (January 13), begin a course of five lectures on "Colonial Animals, their Structure and Life Histories"; Prof. Dewar will, on Thursday (January 15), begin a course of eleven lectures on "The New Chemistry"; and Dr. Waldstein will, on Saturday (January 17), begin a course of three lectures on "Greek Sculpture from Pheidias to the Roman Era." The Friday evening meetings will begin on January 16, when Prof. Tyndall will give a discourse on "Living Contagia."

According to the *North China Herald* there died a few months ago at Pekin, the greatest Chinese mathematician of the present century. His name was Li Shan-lan, and he was Professor of Mathematics at the Foreign College in the Chinese Capital. He differed from the mathematicians of Europe in this respect, that he denied the non-existence of a point. "A point," said Prof. Li, "is an infinitesimally small cube," and in saying this he only reproduced the theories of Chinese sophists 2000 years ago. A great writer of that age put into the mouth of a sophistical being, whom he called the god of the northern sea, the following theory, which has its bearing on Prof. Li's heterodox views about a mathematical point: Subtlety is the occult part of the minute. Be a thing subtle or gross, it seems to me that it must have a form. A formless or unsubstantial thing cannot be distinguished as gross or subtle, discriminate as minutely as you will. What can be spoken of is the gross or palpable part of an entity; what can be imagined only is its subtle part or essence; but I take it that what is neither gross nor subtle can neither be talked of nor imagined.

M. Lauth, the superintendent of the porcelain factory at Sèvres, is said to have discovered a new porcelain, which is far superior to the famous old Sèvres. After ten years' experiment and investigation he thinks he has produced a porcelain identical with that of China. Not only does it lend itself to artistic decoration, but it takes all kinds of glazes, and surpasses in beauty the colours obtained in China.

A proposition to connect Sicily with the mainland, by a submarine railway from Messina to Reggio, has been made by the Society of Engineering of Venice. It has been laid before the Minister of Public Works, who has referred it to a technical commission. A project by the French engineer who constructed the first railways in Rome to build a suspension bridge across the Straits of Messina, was laid at the time before Francis II.; but Garibaldi's campaign in Sicily, and the subsequent political events, caused it to be put aside.

We learn from an Adelaide paper of November 3, 1884, that Mr. Clement L. Wragge has now extended his plan of operations on Mount Lofty, and has established, as a further experiment, a substantially equipped meteorological observatory there. At the Torrens Observatory readings are taken in direct connection with the observations on the Mount, 2350 feet.

Prof. Sylvester asks us to state that in his article "On the Genesis of an Idea," the footnote on p. 36, left-hand column, should read:—"It is one of Descartes' 'self-evident primary truths' that nothing which has happened could not have happened or have happened otherwise." The words "have happened" unfortunately dropped out.

The additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii* ♂) from South Africa, presented by Mr. J. W. Moon; a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Mrs. M. E. Mackern; a Brown Hyæna (*Hyæna brunnea*) from South Africa, presented by Mr. R. W. Murray; a Nubian Ibex (*Capra nubiana* ♂), a —— Ibex (*Capra* —— ♂), a Domestic Goat (*Capra hircus* ♀) from the Soudan, presented by Mrs. Laing; seven Angulated Tortoises (*Chersina angulata*), two Hoary Snakes (*Coronella cana*), a Many-spotted Snake (*Coronella multimaculata*), a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Golden Eagle (*Aquila chrysaetos*), European, deposited; a —— Gibbon (*Hylobates* ——) from Siam, purchased.

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF 1914, AUGUST 20–21.—There have been given in this column, at various times, particulars of the track of the central line in a number of the total eclipses of the sun that will occur during the next thirty years. To these may be added similar notes on the eclipse of August 20–21, 1914, which is a return of that of July 29, 1878, so extensively observed in the United States. The elements of this eclipse are very approximately as follow:—

G.M.T. of Conjunction in R.A. 1914, August 20, 23h. 55m. 3s.

	°	′	″	
R.A.	149	45	36·1	
Moon's hourly motion in R.A. ...		33	7·5	
Sun's ,, ,, ...		2	18·9	
Moon's declination	13	9	42·2	N.
Sun's ,, ...	12	19	29·1	N.
Moon's hourly motion in declination		15	16·0	S.
Sun's ,, ,, ,, ...			49·7	S.
Moon's horizontal parallax		59	17·6	
Sun's ,, ,, ...			8·7	
Moon's geocentric semi-diameter ...		16	11·0	
Sun's ,, ,, ,, ...		15	51·1	

Hence it will be found that the

	°	′			°	′	
Total eclipse begins in long.	120	42	W.,	lat.	71	21	N.
,, ,, at 0h. ,,	2	0	E.	,,	70	42	N.
,, ,, ends ,,	70	26	E.	,,	23	52	N.

In traversing the European continent, the central line runs through the points

Long.	Lat.	Long.	Lat.
12° 33′ E. ...	65° 48′ N.	30° 33′ E. ...	50° 35′ N.
14 39 ,, ...	64 32 ,,	32 53 ,, ...	48 2 ,,
22 44 ,, ...	58 23 ,,	39 12 ,, ...	41 23 ,,
27 30 ,, ...	53 48 ,,	46 28 ,, ...	34 52 ,,

The first of these points is close upon the coast of Norway, at the Island of Alstahoug, and on making a direct calculation for it, the totality is found to commence at 0h. 54m. 19s. local mean time, continuing 1m. 59s., with the sun at an altitude of 37°, and this will be about the most favourable position for observation.

THE MINOR PLANETS.—That part of the *Berliner Astronomisches Jahrbuch* for 1887, containing its speciality, the ephemerides of the small planets for 1885, has been issued in advance of the publication of the volume. There are approximate places for every twentieth day of 237 out of the 244 now known, with accurately calculated opposition-ephemerides of 19. The most reliable elements of the orbits of these bodies to No. 237 inclusive are appended. *Æthra* continues at a distance of less than 1·0 from the earth until February 11, and if the orbit had been more closely determined, would have afforded a favourable opportunity of applying the method of finding the solar parallax suggested by Prof. Galle, as the planet has been a ninth magnitude at this opposition. *Eva*, *Stephania*, and *Agathe*, also approach the earth during the present year, within her mean distance from the sun; on August 10 *Stephania* will be at a distance of only 0·76, magnitude 11½.

Æthra has the least perihelion distance of the group, 1·604, while *Andromache*, with a considerable excentricity, has the greatest aphelion distance, 4·726, so that the orbits of the 244 planets extend over a space of 3·122, the earth's mean distance from the sun being taken as unity. The longest period of revolution occurs in the case of *Hilda*; it is yet doubtful which has the shortest period; No. 149 *Medusa* is credited with it at present, but until this member of the group has been re-observed, the point is perhaps doubtful. The most recently detected planet appears to have the shortest revolution next to *Medusa*, judging from the elements in the last circular of the *Berliner Jahrbuch*.

THE BRIGHTNESS OF SATURN.—Dr. G. Müller, of the Observatory at Potsdam, notifies in a recent number of the *Astronomische Nachrichten*, that since the year 1878 he has made regular photometric observations on Saturn, the main result of which he states to be, that when the earth is at an elevation of 26° above the plane of the ring, the planet's light is 2·4 times greater than when the earth is in that plane, or, in other words, that the brightness of Saturn's rings, when the earth is 26° from their plane, amounts to 58·3 per cent. of the brightness of the whole Saturnian system.

ENCKE'S COMET.—This comet appears to have been re-observed both in Europe and the United States; a somewhat doubtful observation by Dr. Tempel at Florence shows that the predicted elements will require probably but small correction. Taking aberration into account, the calculated position on December 13 differed from that observed, + 1′·1 in right ascension, and + 1′·2 in declination; the theoretical intensity of light on this date was 0·193. In 1852, when the perihelion passage occurred a week only later than in the present year, the comet was first observed on January 9, the intensity of light being 0·228.

GEOGRAPHICAL NOTES

THE lectures given under the auspices of the Paris Geographical Society last spring were so successful, that they are to be resumed this year. The first will be given by M. Janssen, on January 13, on the universal meridian. The others will be, by Prof. de Lapparent, on January 27, on the formation and development of the earth's crust; February 3, M. Bouquet de la Grye, the oceans; February 10, Dr. Hamy, man; March 3, M. Himly, the conquest of the globe; March 10, M. Levasseur, the riches of the globe; March 24, M. Louis Simonin, the great lines of navigation; March 31, M. Michel, railways and their relation to geography. These lectures are not free even to members, the charge for the course to such being fifteen francs, and twenty francs to outsiders. Some of the lectures will be illustrated with projections on the screen, and the success of the enterprise is so assured that a third series has already been arranged for in 1886.

MR. H. H. JOHNSTON writes as follows to the *Times*:—"The Kilimanjaro Expedition which I have just undertaken has resulted in a pleasant and healthy sojourn in one of the most beautiful and interesting regions in the world. I arrived at the mountain in the beginning of June, and settled first in Mandara's territory, on the southern slopes. Here I built a small town of about twenty houses and passed four months in collecting and making numberless excursions right and left. The climate was that of a Devonshire summer, provisions were abundant, cheap, and of great variety, and I was only fearful lest this delightful region might become to me a Capua, and deter me from the more important work that awaited me at a higher level than could be attained within the limits of Mandara's kingdom. Accordingly, when I had received from the coast a reinforcement of hardier men, I established myself at a height of 11,000 feet, and here built an even larger village than my settlement at Moshi. This was on a splendid site. A mountain torrent dashed past our circle of pretty thatched cottages, which surmounted a grassy knoll above the stream; to the south of us spread a wondrous prospect of sun-lit plains and distant rivers—a veritable map of Eastern Africa—and to the north rose the unspeakably grand summits of the mountain mass—Kibô, a dazzling dome of virgin white, and Kimawenzi, a piebald peak of black, jagged rocks, seamed and flecked with snow. From this settlement I constantly ascended as far as I was able in one day's journey, but the difficulties which lay in the way of a complete ascent of either peak arose from the impossibility of inducing any of my followers to accompany me beyond 14,000 feet, for above this altitude they suffered so keenly from cold and mountain sickness that no persuasion or bribes would induce them to ascend any higher, far less to carry any of my *impedimenta*. Consequently, I could never get beyond a certain distance from the settlement, the cold not permitting me to risk the chance of being benighted in the snow. I reached, however, an altitude of 16,200 feet, a little more than 2000 feet from the summit of Kibô, (18,800 feet high). I found warm springs at 14,400 feet, detected no signs of glacial action, and was somewhat disappointed with the paucity of plants growing at the snow line. Birds were very rare above 10,000 feet, and very abundant below. Lizards and chameleons existed (and frogs also) up to the very snow. Hyraxes (the hyrax is the coney of Scripture) were common between 8000 and 13,000 feet, and I fancy are represented by a new species. Buffaloes and elephants ascended to 14,000 feet. The thunderstorms that frequently rage round the upper slopes of the mountain are terrific, and the wind at times is so violent that no one can keep their feet. The natives who

inhabit Kilimanjaro up to 6000 feet, are fairly tractable, and have a passionate love of trade, which with them is the great pacifier. They go absolutely naked, or if any clothing is worn in the way of ornament it rarely goes beyond leather capes for the shoulders. They all speak dialects belonging to the great Bantu group of languages. I have studied carefully several of them, and have, I believe, discovered some most interesting points in their construction likely to throw considerable light on the archaic forms of Bantu prefixes. I may add that, after a very happy sojourn in the lovely forest region of Taveita at the foot of the mountain, I was compelled to return most reluctantly to the coast at the end of November owing to the exhaustion of my funds. I left Kilimanjaro with great regret, and on my homeward journey my thoughts were persistently directed to my whilom African home, rather than to an unwilling and too early return to civilisation. My collections have safely reached this country, and will, I hope, be sufficient to indicate the true character and relationships of the fauna and flora of Kilimanjaro."

The death is announced at Lübeck of Dr. Robert Avé-Lallemant, at one time a well-known traveller in South America. He became surgeon to the Novara expedition, which, however, he left at Rio, in order to devote himself to exploration in Brazil. In 1858 he went to Rio Grande do Sul, where he commenced his journey into Southern Brazil, during which he visited Bonpland, a few months before his death, in his lonely ranche in Paraguay. He crossed the Uruguay Allegrette, San Gabriel, and Cacupava to the Jacuy. From San José he went along the coast to Laguna, visited the sources of the Uruguay, and returned to San José through forests still unknown to travellers. This journey lasted about a year, and soon after his return he again set out to travel through the northern provinces. Landing at Bahia, he followed the coast to the Mucury river. Here he discovered the shocking condition of some of the German colonies. Thence he went to Pernambuco, and ascended the Amazon to Tabatinga, on the Peruvian frontier. On these journeys he published two large works ("Reise durch Süd Brasilien, 1859," and a similar work on North Brazil), and numerous smaller ones. They give no new geographical discoveries or exact measurements, or the results of scientific investigation, but they contain valuable information respecting the country, the fauna and flora, and condition of the people. The later years of his life were spent in medical practice in his native city.

According to *L'Exploration*, the Argentine authorities are sending an expedition to the Chaco. It consists of 200 men, divided into three columns, operating from different points, but meeting at Cangayé, a centre almost equally distant from Salta and Paraguay. The object is both military and scientific. It is desired to secure the possession of this vast territory to the Argentine Republic against the Indians, who are again masters there. Six topographical commissions are attached to the expedition in order to study the country, prepare maps, and also, it is said, to investigate the possibility of a railway as far as Oran, in the province of Salta. The investigation of the rivers, for which the gunboat *Pilcomayo* is sent, has been delayed by the low state of the water, but recent rains will now enable that work to be proceeded with. If the result should be the demonstration of the suitability of the *Pilcomayo* to navigation, not only will a great service be rendered to topographical science, but by assuring communications between Bolivia and the Rio Paraguay, a great economical revolution will, it is expected, be produced in these regions.

EXPERIMENTS SUITABLE FOR ILLUSTRATING ELEMENTARY INSTRUCTION IN CHEMISTRY

Professors Sir H. E. Roscoe and W. J. Russell, by direction of the Lords of the Committee of Council on Education, have recently prepared, for the assistance of teachers of science schools and classes, an outline of experiments in chemistry. As this subject is now under discussion, we are glad to be able to give the outline *in extenso* in Nature.

The notes have been prepared as some guide to the teachers as to the general character of the course of instruction expected in the elementary stage; they include instruction that should on no account be omitted, but must be considered rather as suggestive than exhaustive.

I.—*Combustion and Chemical Combination*

1. Burn a taper in a clean glass bottle. Show the presence of a colourless gas, differing in properties from common air by yielding a turbidity with lime-water.

2. Hold a bright glass over a burning candle and show the formation of water.

Explain what is meant by chemical change, and state that chemistry is an experimental science.

3. Make similar experiments with a petroleum or paraffin lamp.

4. Show that coal-gas also yields the same products by passing the products of combustion through lime-water and by collecting the water.

5. Explain the difference between mechanical mixture and chemical combination; and illustrate by a mixture of finely-divided copper and flour of sulphur, and the effect of heat upon the same.

6. Experiment to show that chemical change consists of a change in the properties of matter and that no loss of matter takes place. Suspend lamp chimney, partly filled with lumps of caustic soda, from the arm of a balance. Place short piece of candle in the lower part of the glass and counterbalance. Light the candle. Explain the increase in weight.

7. Heat is evolved when chemical combination takes place. Pour water on to quicklime. Refer also to experiments 1 and 3.

8. Combustibles and supporters of combustion. The purely relative character of these terms. Ordinary combustion the union of atmospheric oxygen with a body termed the combustible, or with one or more of its constituents, heat being developed, as in all cases where two or more bodies combine. Illustrate by showing that air will burn in coal-gas just as well as coal-gas will burn in air.

II.—*Air*

1. Existence of atmosphere, felt in winds.

2. Weight of air shown by means of a flask exhausted by the air-pump.

3. Burn phosphorus in air.

4. Burn phosphorus in confined volume of air and show diminution in bulk.

5. Show that some diminution takes place slowly when a stick of phosphorus is exposed to air at ordinary temperatures.

6. Test residual gas (N) with a burning taper.

7. Show that phosphorus burnt in air increases in weight.

8. Allow iron borings moistened with sal ammoniac to rust in a confined volume of air and introduce burning taper into residual gas (N).

9. Show that iron filings, suspended by a magnet hanging on one scale of a balance, increase in weight on heating.

10. Strongly heat the red substance which may be formed by gently heating mercury in the air. Collect and test the gas (O) with a glowing splinter of wood.

11. Add the gas thus obtained to the residue obtained in experiment 4 or 8 so as to make up the original volume of air, and show that a taper burns in this mixture as in common air.

12. Refer to numbers giving exact analysis of air, calling especial attention to the fact that it varies slightly in composition.

Also explain that no obvious change, such as increase of temperature or alteration of bulk, occurs when oxygen and nitrogen are mixed. Also that air has the properties of a mixture, and that when water is shaken up with air a portion of that air dissolves, the residue being found to contain relatively less oxygen than the original air, whilst the dissolved portion contains relatively more oxygen, and that this could not be the case if the air were a compound. Consequently it is a mixture and not a chemical compound.

13. It is important that these experiments should be made and their explanation given so as to teach the student how the composition of air is ascertained by experiment, and in a similar manner how oxygen was discovered by Priestley, and how the composition of the air and the part which oxygen plays in the phenomena of combustion were experimentally demonstrated by Lavoisier.

III.—*Effects of Animal and Vegetable Life upon the Atmosphere*

1. Show that by drawing air into the lungs through lime-water a very faint, if any, precipitate is produced; but that on expiring air from the lungs through another portion of lime-water a copious precipitate is soon formed.

2. Show the production of carbon dioxide by the oxidation of ordinary articles of food, as by heating small quantities of the dried substance, such as sugar, bread, or meat, with copper oxide.

3. Show that carbon dioxide exists in the air by pouring clear lime-water into a shallow vessel exposed to air, and explain that this small quantity of carbon dioxide serves as the main food of the plants that grow on the earth.

4. Expel air from water by boiling, and explain how fish and aquatic plants are thus provided with oxygen and carbonic acid.

5. Explain that plants eliminate and animals require oxygen. That animals take in oxygen from the air, and give out carbonic acid. That plants possess the power under the influence of light of assimilating carbon from carbon dioxide and liberating the oxygen. Explain that thus the balance of oxygen and carbon dioxide in the atmosphere is maintained.

6. Illustrate the action of plants by the formation of bubbles of oxygen when a fresh plant is exposed to the action of light in water containing carbonic acid in solution.

IV.—*Water*

1. Illustrate the three states of matter, the solid, the liquid, and the gaseous, with ice, water, and steam, and point out that the difference is caused by increase or diminution in the amount of heat present.

2. Composition of water. Decompose water by the electric current. Collect the two gases separately in a voltameter, and exhibit their properties.

3. Show formation of water by explosion of a mixture of hydrogen (two volumes) and oxygen (one volume) in a soda-water bottle.

4. Explode soap-bubbles inflated by a mixture of hydrogen and oxygen in the above proportions.

5. Throw potassium or sodium into water, and collect the hydrogen.

6. Pass steam over red-hot iron, collect the gas and show that it is hydrogen.

7. Show that the same gas may be obtained by dissolving zinc clippings or iron turnings in dilute sulphuric acid.

8. Demonstrate the properties of hydrogen :
 (*a*) Its combustibility.
 (*b*) Its lightness.
 (*c*) That a candle will not burn in it.
 (*d*) That water is formed when it burns in air.

9. Composition of water. Pass oxygen over red-hot copper, and show by weighing before and after that the weight increases.

10. Pass hydrogen over the copper oxide thus produced, heating gently. Collect the water, and show that the copper oxide has been entirely reduced, the tube weighing the same as before passing the oxygen through it.

11. Determine the composition of water by weight by passing dry hydrogen over half an ounce of copper oxide, and collecting the water in a weighed chloride of calcium tube. Show approximately that water contains two parts by weight of hydrogen to sixteen parts by weight of oxygen.

12. Note the first law of chemical combination : that chemical compounds, such as water, always contain their components in the same unvarying proportions.

13. Contrast the properties of water with those of its constituents on the one hand, and the properties of air with those of its constituents on the other.

14. Call attention to air and water as illustrations of the difference between a mixture and a compound, and quote oxygen, nitrogen, and hydrogen as examples of elementary bodies.

15. Separation of impurities from water by filtration and distillation. Preparation of fresh water from salt water.

16. Experiments illustrating solution and crystallisation. Soluble substances, as sugar, washing soda, alum ; slightly soluble substances, as gypsum or plaster of Paris ; insoluble substances, as chalk, flint, and sand.

17. Crystallise carbonate of soda, and sulphate of copper.

V.—*Oxygen and Ozone*

1. Prepare oxygen by heating
 (*a*) Oxide of mercury.
 (*b*) Potassium chlorate.
 (*c*) Mixture of potassium chlorate, and either manganese dioxide, copper oxide, or ferric oxide.

2. Show the re-ignition of a splinter of red-hot wood and glowing wick of taper.

3. Burn charcoal in oxygen, and show the formation of carbon dioxide.

4. Burn phosphorus simultaneously in air and in oxygen.

5. Burn watch-spring in oxygen.

6. Show that iron does not rust in dry oxygen.

7. *Ozone.*—Describe and demonstrate the formation of ozone by submitting oxygen to the silent electric discharge.

8. Describe and demonstrate the properties of ozone which distinguish it from ordinary oxygen, such as its action on metallic mercury, on indigo solution, or on potassium iodide and starch. Also its change to ordinary oxygen when passed through a heated glass tube.

9. Explain the difference in density between oxygen and ozone.

VI.—*Combining Weights ; Names and Symbols of the Elements ; Chemical Calculations, &c.*

1. Exhibit list of the elements, distinguishing (by means of the type) the non-metals from the metals ; and, again, the more commonly occurring metals from those which are rarer.

2. Describe the occurrence of these elements in the air, in the sea, and in the solid crust of the earth.

3. Write up the results of the quantitative analysis of potassium chlorate. Explain that this is the result of experiment, and demonstrate the fact that, when heated, an unalterable weight of oxygen is given off and a given unalterable weight of potassium chloride remains behind.

4. Dissolve a crystal of pure chlorate of potassium, and the residue of chloride from heating chlorate, in two separate glasses, and show the difference in the reaction with silver chloride.

5. Explain the meaning of the term chemical symbol, and chemical formula of the salt, referring afterwards to the combining weights of the elements.

6. Explain the mode of determining the formula from the percentage composition.

7. Method of calculating the quantity of oxygen from potassium chlorate (and from manganese dioxide).

VII.—*Acids, Bases, and Salts*

1. Burn sodium in oxygen ; dissolve the product in water ; give the formula of the oxide. Express the action of water upon it by an equation.

2. Act on water with sodium, and collect the hydrogen. Explain by equation that the same substance, sodium hydrate or hydroxide, or caustic soda, is formed, as in experiment 1.

3. Burn sulphur in a current of oxygen, and show the product fumes slightly in the air. Explain that it is a mixture of sulphur dioxide and trioxide. Pass the gas thus obtained into water.

4. Add litmus solution to the solutions obtained in experiments 2 and 3, and show that on adding the one solution to the other the colour is changed, or a point is reached where a further addition of the one has no effect, whereas a minute addition of the other at once changes the colour. Explain the action by an equation.

5. Explain that the compound formed from the sodium oxide and water is termed an alkali, or alkaline or basic hydroxide, and the oxide from which it is formed an alkaline or basic oxide ; that the compound formed from the sulphur dioxide and water is termed an acid hydroxide or acid, and the original oxide an acid forming oxide or anhydride.

6. Explain that sodium hydroxide and sulphurous acid may be taken as representative of the two classes into which hydroxides are divided.

7. Explain that by the action of the one upon the other a salt is formed. Exhibit a white crystalline salt, *e.g.* sodium sulphate.

VIII.—*Hydrogen*

1. Prepare hydrogen by the action of dilute sulphuric acid on zinc.

2. Show that it is not obtained by the use of pure zinc (amalgamated zinc is best used), and illustrate the effect of impurity by adding a drop or two of a lead or copper salt.

3. Prepare hydrogen by dissolving zinc or aluminium in sodium hydroxide.

4. Point out that whereas sodium displaces hydrogen from water at ordinary temperature, and that iron does so at a red heat, copper is without any action at any temperature.

5. Give equations for the various methods here indicated for obtaining hydrogen.[1]

6. Explain fully in detail the methods of chemical calculation, and make the pupils thoroughly understand the methods of calculating quantities.

7. Demonstrate the physical properties of hydrogen, especially its lightness and diffusibility.

8. Compare the heating powers of jet of hydrogen burning in air and in oxygen. Explain the difference.

9. Describe and (if possible) demonstrate the construction and use of the oxy-hydrogen blowpipe.

10. Explain what is meant by heat of combustion, and define the term "heat-unit." Show for this purpose side by side 18 grammes of water and the quantity of water which would be raised 1° C. in temperature by the heat developed in the formation of this quantity of water from its elements.

11. Point out that hydrogen is a powerful reducing agent, illustrating this by the reduction of oxide of iron.

12. Show that nascent hydrogen, or hydrogen at the moment of its liberation from its compounds, frequently produces effects that hydrogen in the free state does not. Bubble hydrogen through ferric chloride solution and show that no discolorisation takes place. Place it in contact with zinc and dilute sulphuric acid and the colour disappears.

13. Explain the term nascent as applied to hydrogen and other gas at the moment of its liberation from one of its compounds, and distinguish between the atom of nascent hydrogen and the molecule of free hydrogen.

IX.—*Hydrochloric Acid and Chlorine*

1. Explain with equation and show the action of sulphuric acid on common salt. Collect the escaping gas by downward displacement and show its solubility in water.

2. Hold piece of paper dipped in ammonia solution in the gas.

3. Saturate water with the gas, noting that its volume increases and that considerable heat is developed.

4. Exhibit the effects produced by adding the solution to litmus and to silver nitrate solution.

5. Show that it has no action on indigo, or on a mixture of potassium iodide and starch solution.

6. Pass the gas over red-hot iron and show the production of hydrogen.

7. *Chlorine.*—Heat oxide of manganese with the solution of hydrochloric acid obtained in experiment 3, and collect several jars of the escaping chlorine by downward displacement. Give the equation.

8. Pass some of the gas into water. Exhibit the yellow colour of the solution and show that it precipitates silver nitrate and bleaches litmus and indigo.

9. Burn a jet of hydrogen in chlorine. Show the disappearance of the yellow-coloured gas.

10. Moisten some paper with a few drops of turpentine and throw it into a jar of chlorine. Point out the formation of hydrochloric acid and the deposition of carbon.

11. Explode a mixture of equal volumes of hydrogen and chlorine.

12. Point out how these experiments show that the gas produced in experiment 1 is a compound of chlorine and hydrogen. Give the symbol and atomic weight of chlorine, and state the composition of hydrochloric acid gas by weight and volume.

13. Explain the production of chlorine from common salt, sulphuric acid, and manganese dioxide. Give equations, and instruct the students in the calculations of quantities.

14. Show the combustion in chlorine, of phosphorus, antimony, and copper, and demonstrate its power to displace bromine and iodine from their compounds with metals.

15. Electrolysis of hydrochloric acid solution, and explain the fact of the evolution of equal volumes of its constituent gases.

16. Explain the bleaching action of chlorine as being due to the readiness with which it combines with hydrogen and that it thus acts as an oxidising agent. In illustration of this, show that a piece of dry turkey red cloth when placed in dry chlorine is not bleached.

X.—*Nitrogen and Ammonia*

1. The production of nitrogen from the air and the examination of its properties may here be repeated.

2. Describe and (if possible) demonstrate the production of ammonia by passing sparks from an induction coil or electric machine through a mixture of nitrogen and hydrogen. Explain that the reaction is not complete unless the ammonia is withdrawn as it is formed, owing to the fact that ammonia is readily decomposed by heat.

3. Prepare ammonia by heating an ammoniacal salt with slaked lime. Collect by upward displacement and over mercury, and show extreme solubility in water.

4. Demonstrate and explain its combination with hydrochloric acid, and show the volatility of sal ammoniac.

5. Show that the aqueous solution of ammonia behaves in the same way as a solution of sodium hydroxide, turning red litmus blue, neutralising acids, and forming precipitates in solutions of metals (copper, iron, and zinc salts, for example) of the same composition as those produced by sodium hydroxide. Explain that on this account it is considered that the ammonia solution contains ammonium hydroxide.

6. Pass dry ammonia gas over red-hot copper oxide and show the production of water and metallic copper.

7. Pass air and ammonia gas simultaneously over red-hot copper as a method of preparing nitrogen.

XI.—*Nitric Acid and the Oxides of Nitrogen*

1. Explain on the blackboard the composition by weight of the five distinct oxides of nitrogen as illustrative of the law of chemical combination in multiple proportions, and as a deduction from this, explain Dalton's atomic theory and state clearly what is meant by an atom. Demonstrate with a series of blocks labelled with the symbols of the different elements how this explains the observed facts of combination in multiple proportions.

2. Make clear to the student the difference between atom and molecule, and explain atomic weight and molecular weight of (1) hydrogen; (2) oxygen, ozone; (3) chlorine; and then of compounds such as (4) hydrochloric acid; (5) water; (6) ammonia.

3. Describe and (if possible) demonstrate the formation of the red fumes of nitric peroxide on passing an electric spark through air.

4. Preparation of nitric acid from nitre and sulphuric acid. Explain the reaction by an equation.

5. Calculation of quantities to be carefully gone into.

6. Exhibit nitre, nitrate of soda, sulphate and bisulphate of potash, and sulphate and bisulphate of soda.

7. Show the oxidising action of nitric acid by dropping it on to some red-hot charcoal.

8. Oxidising action of nitric acid on metallic tin and metallic copper.

8A. Deflagrate mixture of nitre and charcoal.

9. Show the decomposition of nitric acid when heated by dropping it into the bowl of a clay tobacco pipe, the stem of which is strongly heated, collecting the gas over water and testing with a flaming splinter of wood.

10. Heat potassium nitrate and collect the gas (O).

11. Prepare nitric oxide from residue in experiment 10 by treating with dilute sulphuric acid. Explain decomposition o nitrous acid into nitric oxide and nitric acid.

12. Prepare nitric oxide by action of nitric acid on copper turnings. Collect the gas. Explain the reaction.

13. Exhibit the direct combination of nitric oxide with oxygen. Note the formation of red fumes of nitrogen peroxide and their immediate absorption by water.

14. Show that flame of a taper is extinguished in nitric oxide, and that feebly burning phosphorus is also extinguished, but that brightly burning phosphorus continues to burn, and with greater brilliance than in ordinary air. Explain this.

15. Preparation of nitrous oxide. Neutralise nitric acid with ammonia. Evaporate the solution and obtain the solid salt. Show the preparation of nitrous oxide with this residue. Collect the gas over warm water. Give equation. Explain that nitrous oxide is readily soluble in cold water.

16. Show that like oxygen, nitrous oxide supports the combustion of a taper, and explain that this is caused by the decomposition of the gas, and the union of the constituents of the taper with the oxygen of the nitrous oxide, and liberation of the nitrogen.

17. Also show that phosphorus and strongly ignited sulphur burn in the gas, but that feebly ignited sulphur is extinguished. Explain this.

18. Point out the distinction between nitrous oxide and oxygen: (1) the solubility of nitrous oxide in cold water, (2) the production of nitrogen when bodies burn in it, (3) the fact that nitric oxide does not produce with it red fumes, as is the case with oxygen.

19. Prepare nitrogen from ammonium nitrite (*i.e.* a mixture of potassium nitrite and ammonium chloride).

20. Explain how, in the above experiments, the gradual deoxidation of nitric acid yields the several oxides of nitrogen, and lastly, nitrogen itself.

XII.—*Sulphur*

1. Exhibit the different forms of sulphur: flour of sulphur, brimstone or stick sulphur, and crystallised native sulphur.

2. Dissolve sulphur in bisulphide of carbon, and obtain crystals by spontaneous evaporation. Indicate the identity of this form with the naturally occurring crystals, and its difference from that obtained by fusing sulphur and allowing the mass to cool.

3. Explain what is meant by allotropic modification, and point out how the one form of crystal passes into the other.

4. Show the effect of heat upon sulphur melted in a flask. Contrast the brittle mass derived from cooling the sulphur after heating slightly above its melting-point by pouring into cold water, with the plastic mass obtained when cooled in the same way from a high temperature. Point out the changes which occur as the temperature rises, and exhibit the red vapour of sulphur.

5. Show combustion in sulphur vapour. Insert a coil of copper wire into the sulphur vapour, and show that combination occurs.

6. Distil sulphur in a small retort.

7. Pass hydrogen through boiling sulphur, and demonstrate the formation of hydrogen sulphide by its blackening action on lead paper.

8. Exhibit ferrous sulphide and galena (lead sulphide). Prepare hydrogen sulphide (sulphuretted hydrogen) from the former by the action of dilute sulphuric acid. Collect by displacement and prepare a solution of the gas in water.

9. Show the combustible nature of hydrogen sulphide by burning a jar of the gas, and point out the deposition of sulphur due to incomplete combustion. Demonstrate and explain the decomposition of hydrogen sulphide by chlorine, and show the deposition of sulphur when its solution is allowed to stand exposed to the air and light.

10. Demonstrate the value of hydrogen sulphide as a means of separating the metals into groups, by adding the solution or passing the gas into solutions of the various metals, as, for example, arsenious acid, copper sulphate, lead nitrate, antimony chloride, zinc sulphate, ferrous sulphate, and magnesium sulphate.

Write down the equations in each case.

11. Prepare sulphur dioxide by heating copper with sulphuric acid and collect the gas.

12. Illustrate the condensation of a gas into a liquid by passing sulphur dioxide into a glass tube surrounded by a freezing mixture of ice and salt.

13. Pass the gas into water and demonstrate the acid properties of the solution.

14. Prepare sulphur trioxide from fuming Nordhausen sulphuric acid. Add it to water and compare its behaviour with that of the dioxide under similar circumstances.

15. Describe the formation in the above experiment of sulphuric acid, explain the properties of oil of vitriol, demonstrating its affinity for water as exhibited by the great heat evolved when the two liquids are mixed.

16. Explain the barium chloride test for sulphuric acid.

17. Add barium chloride to a solution of sulphurous acid, and then nitric acid.

18. Explain that in consequence of the readiness with which sulphurous acid takes up oxygen it acts as a bleaching agent and as a powerful reducing agent.

XIII.—*Carbon*

1. Show the presence of carbon (charcoal) in wood by carbonising a splinter of wood in a test-tube; and in white sugar by pouring strong sulphuric acid on to a syrupy solution.

2. Describe the properties and modes of occurrence of the three allotropic modifications of carbon: (*a*) the amorphous form (lamp-black and charcoal), and the two crystalline forms, (*b*) graphite, and (*c*) diamond. Describe the octahedral forms of the crystal of diamond and show glass or wood models.

3. Explain that the same weight of each of these substances when burnt gives the same weight of the same product (carbon dioxide).

4. Calculate the weight of carbon dioxide obtained from a given weight of any one of these forms.

5. Prepare carbon dioxide by treating chalk or carbonate of soda (washing soda) with an acid. Prove that the gas thus obtained really obtains carbon by heating a pellet of potassium in the dry gas contained in a small flask.

6. Demonstrate the high specific gravity of carbon dioxide by pouring it from one vessel to another, and showing that it extinguishes a taper.

7. Pass carbon dioxide over red-hot carbon in an iron tube, and show that it loses a part of its oxygen and is converted into carbon monoxide, a combustible gas, which, on combustion, again yields carbon dioxide. Collect the carbon monoxide over water containing caustic soda, and show that the gas does not render lime-water turbid. Then burn it, and show that the residual gas does possess this power.

8. Pass carbon monoxide over red-hot copper oxide to show the formation of carbon dioxide, and explain the use of carbon monoxide as a reducing agent in metallurgical operations.

9. Explain the changes which take place in an ordinary coal fire. Mention the poisonous nature of the carbon monoxide, and state that it is formed in cases of incomplete combustion from insufficient supply of oxygen.

10. Mention heat of combustion of carbon, and of carbon monoxide, and explain the value of the latter as a fuel.

11. Explain the reaction which takes place when carbon dioxide is passed into caustic soda and into lime-water, and explain the formation of a soluble carbonate in the first, and an insoluble carbonate in the second case.

CHARACTERISTICS OF THE NORTH AMERICAN FLORA[1]

WHEN the British Association, with much painstaking, honours and gratifies the cultivators of science on this side of the ocean by meeting on American soil, it is but seemly that a Corresponding Member for the third of a century should endeavour to manifest his interest in the occasion and to render some service, if he can, to his fellow-naturalists in Section D. I would attempt to do so by pointing out, in a general way, some of the characteristic features of the vegetation of the country which they have come to visit,—a country of "magnificent distances," but of which some vistas may be had by those who can use the facilities which are offered for enjoying them. Even to those who cannot command the time for distant excursions, and to some who may know little or nothing of botany, the sketch which I offer may not be altogether uninteresting. But I naturally address myself to the botanists of the Association, to those who, having crossed the wide Atlantic, are now invited to proceed westward over an almost equal breadth of land; some, indeed, have already journeyed to the Pacific coast, and have returned; and not a few, it is hoped, may accept the invitation to Philadelphia, where a warm welcome awaits them—warmth of hospitality, rather than of summer temperature, let us hope; but Philadelphia is proverbial for both There opportunities may be afforded for a passing acquaintance with the botany of the Atlantic border of the United States, in company with the botanists of the American Association, who are expected to muster in full force.

What may be asked of me, then, is to portray certain outlines of the vegetation of the United States and the Canadian Dominion, as contrasted with that of Europe; perhaps also to touch upon the causes or anterior conditions to which much of the actual differences between the two floras may be ascribed. For indeed, however interesting or curious the facts of the case may be in themselves, they become far more instructive when we attain to some clear conception of the dependent relation of the present vegetation to a preceding state of things, out of which it has come.

As to the Atlantic border on which we stand, probably the first impression made upon the botanist or other observer coming from Great Britain to New England or Canadian shores, will be the similarity of what he here finds with what he left behind. Among the trees the White Birch and the Chestnut will be identified, if not as exactly the same, yet with only slight differences—differences which may be said to be no more essential or profound than those in accent and intonation between the British

[1] An Address to the Botanists of the British Association for the Advancement of Science; read at Montreal to the Biological Section, August 29, 1884, by Prof. Asa Gray.

speech and that of the "Americans." The differences between the Beeches and Larches of the two countries are a little more accentuated; and still more those of the Hornbeams, Elms, and the nearest resembling Oaks. And so of several other trees. Only as you proceed westward and southward will the differences overpower the similarities, which still are met with.

In the fields and along open roadsides the likeness seems to be greater. But much of this likeness is the unconscious work of man, rather than of Nature, the reason of which is not far to seek. This was a region of forest, upon which the aborigines, although they here and there opened patches of land for cultivation, had made no permanent encroachment. Not very much of the herbaceous or other low undergrowth of this forest could bear exposure to the fervid summer's sun; and the change was too abrupt for adaptive modification. The plains and prairies of the great Mississippi Valley were then too remote for their vegetation to compete for the vacancy which was made here when forest was changed to grain-fields and then to meadow and pasture. And so the vacancy came to be filled in a notable measure by agrestial plants from Europe, the seeds of which came in seed-grain, in the coats and fleece and in the imported fodder of cattle and sheep, and in the various but not always apparent ways in which agricultural and commercial people unwittingly convey the plants and animals of one country to another. So, while an agricultural people displaced the aborigines which the forest sheltered and nourished, the herbs, purposely or accidentally brought with them, took possession of the clearings, and prevailed more or less over the native and rightful heirs to the soil,—not enough to supplant them, indeed, but enough to impart a certain adventitious Old World aspect to the fields and other open grounds, as well as to the precincts of habitations. In spring-time you would have seen the fields of this district yellow with European Buttercups and Dandelions, then whitened with the Ox-eye Daisy, and at midsummer brightened by the cærulean blue of Chicory. I can hardly name any native herbs which *in the fields and at the season* can vie with these intruders in floral show. The common Barberry of the Old World is an early denizen of New England. The tall Mullein, of a wholly alien race, shoots up in every pasture and new clearing, accompanied by the common Thistle, while another imported Thistle, called in the States "the Canada Thistle," has become a veritable nuisance, at which much legislation has been levelled in vain.

According to tradition the wayside Plantain was called by the American Indian "White-Man's foot," from its springing up wherever that foot had been planted. But there is some reason for suspecting that the Indian's ancestors brought it to this continent. Moreover there is another reason for surmising that this long-accepted tradition is factitious. For there was already in the country a native Plantain, so like *Plantago major* that the botanists have only of late distinguished it. (I acknowledge my share in the oversight.) Possibly, although the botanists were at fault, the aborigines may have known the difference. The cows are said to know it. For a brother botanist of long experience tells me that, where the two grow together, cows freely feed upon the undoubtedly native species, and leave the naturalised one untouched.

It has been maintained that the ruderal and agrestial Old World plants and weeds of cultivation displace the indigenous ones of newly-settled countries in virtue of a strength which they have developed through survival in the struggle of ages, under the severe competition incident to their former migrations. And it does seem that most of the pertinacious weeds of the Old World which have been given to us may not be indigenous even to Europe, at least to Western Europe, but belong to campestrine or unwooded regions farther east; and that, following the movements of pastoral and agricultural people, they may have played somewhat the same part in the once forest-clad Western Europe that they have been playing here. But it is unnecessary to build much upon the possibly fallacious idea of increased strength gained by competition. Opportunity may count for more than exceptional vigour; and the cases in which foreign plants have shown such superiority are mainly those in which a forest-destroying people have brought upon newly-bared soil the seeds of an open-ground vegetation.

The one marked exception that I know of, the case of recent and abundant influx of this class of Old World plants into a naturally treeless region, supports the same conclusion. Our associate, Mr. John Ball, has recently called attention to it. The pampas of South-Eastern South America beyond the Rio Colorado, lying between the same parallels of latitude in the south as Montreal and Philadelphia in the north, and with climate and probably soils fit to sustain a varied vegetation, and even a fair proportion of forest, are not only treeless, but excessively poor in their herbaceous flora. The district has had no trees since its comparatively recent elevation from the sea. As Mr. Darwin long ago intimated: "Trees are absent not because they cannot grow and thrive, but because the only country from which they could have been derived—tropical and sub-tropical South America—could not supply species to suit the soil and climate." And as to the herbaceous and frutescent species, to continue the extract from Mr. Ball's instructive paper recently published in the Linnean Society's *Journal*, "in a district raised from the sea during the latest geological period, and bounded on the west by a great mountain-range mainly clothed with an alpine flora requiring the protection of snow in winter, and on the north by a warm temperate region whose flora is mainly of modified sub-tropical origin—the only plants that could occupy the newly-formed region were the comparatively few which, though developed under very different conditions, were sufficiently tolerant of change to adapt themselves to the new environment. The flora is poor, not because the land cannot support a richer one, but because the only regions from which a large population could be derived are inhabited by races unfit for emigration."

Singularly enough, this deficiency of herbaceous plants is being supplied from Europe, and the in-comers are spreading with great rapidity; for lack of other forest material even apple-trees are running wild and forming extensive groves. Men and cattle are, as usual, the agents of dissemination. But colonising plants are filling, in this instance, a vacancy which was left by Nature, while ours was made by man. We may agree with Mr. Ball in the opinion that the rapidity with which the intrusive plants have spread in this part of South America "is to be accounted for, less by any special fitness of the immigrant species, than by the fact that the ground is to a great extent unoccupied."

The principle applies here also; and in general, that it is opportunity rather than specially acquired vigour that has given Old World weeds an advantage may be inferred from the behaviour of our weeds indigenous to the country, the plants of the unwooded districts—prairies or savannas west and south—which, now that the way is open, are coming in one by one into these eastern parts, extending their area continually, and holding their ground quite as pertinaciously as the immigrant denizens. Almost every year gives new examples of the immigration of campestrine western plants into the Eastern States. They are well up to the spirit of the age: they travel by railway. The seeds are transported, some in the coats of cattle and sheep on the way to market, others in the food which supports them on the journey, and many in a way which you might not suspect, until you consider that these great roads run east and west, that the prevalent winds are from the west, that a freight-train left unguarded was not long ago blown on for more than one hundred miles before it could be stopped, not altogether on down grades, and that the bared and mostly unkempt borders of these railways form capital seed-beds and nursery-grounds for such plants.

Returning now from this side-issue, let me advert to another and, I judge, a very pleasant experience which the botanist and the cultivator may have on first visiting the American shores. At almost every step he comes upon old acquaintances, upon shrubs and trees and flowering herbs, mostly peculiar to this country, but with which he is familiar in the grounds and gardens of his home. Great Britain is especially hospitable to American trees and shrubs. There those both of the eastern and western sides of our continent flourish side by side. Here they almost wholly refuse such association. But the most familiar and longest-established representatives of our flora (certain western annuals excepted) were drawn from the Atlantic coast. Among them are the Virginia Creeper or Ampelopsis, almost as commonly grown in Europe as here, and which, I think, displays its autumnal crimson as brightly there as along the borders of its native woods where you will everywhere meet with it; the Red and Sugar Maples, which give the notable autumnal glow to our northern woods, but rarely make much show in Europe, perhaps for lack of sharp contrast between summer and autumn; the ornamental Ericaceous shrubs, Kalmias, Azaleas, Rhododendrons, and the like, specially called American plants in England, although all the Rhododendrons of the finer sort are half Asiatic, the hardy American species

having been crossed and recrossed with more elegant but tender Indian species.

As to flowering herbs, somewhat of the delight with which an American first gathers wild Primroses and Cowslips and Foxgloves and Daisies in Europe, may be enjoyed by the European botanist when he comes upon our Trilliums and Sanguinaria, Cypripediums and Dodecatheon, our species of Phlox, Coreopsis, &c., so familiar in his gardens; or when, crossing the continent, he comes upon large tracts of ground yellow with Eschscholtzia or blue with Nemophilas. But with a sentimental difference: in that Primroses, Daisies, and Heaths, like nightingales and larks, are inwrought into our common literature and poetry, whereas our native flowers and birds, if not altogether unsung, have attained at the most to only local celebrity.

Turning now from similarities, and from that which interchange has made familiar, to that which is different or peculiar, I suppose that an observant botanist upon a survey of the Atlantic border of North America (which naturally first and mainly attracts our attention) would be impressed by the comparative wealth of this flora in trees and shrubs. Not so much so in the Canadian Dominion, at least in its eastern part; but even here the difference will be striking enough on comparing Canada with Great Britain.

The Coniferæ native to the British Islands are one Pine, one Juniper, and a Yew; those of Canada proper are four or five Pines, four Firs, a Larch, an Arbor-Vitæ, three Junipers, and a Yew—fourteen or fifteen to three. Of Amentaceous trees and shrubs, Great Britain counts one Oak (in two marked forms), a Beech, a Hazel, a Hornbeam, two Birches, an Alder, a Myrica, eighteen Willows, and two Poplars—twenty-eight species in nine genera, and under four natural orders. In Canada there are at least eight Oaks, a Chestnut, a Beech, two Hazels, two Hornbeams of distinct genera, six Birches, two Alders, about fourteen Willows and five Poplars, also a Plane tree, two Walnuts, and four Hickories; say forty-eight species, in thirteen genera, and belonging to seven natural orders. The comparison may not be altogether fair; for the British flora is exceptionally poor, even for islands so situated. But if we extend it to Scandinavia, so as to have a continental and an equivalent area, the native Coniferæ would be augmented only by one Fir, the Amentaceæ by several more Willows, a Poplar, and one or two more Birches;—no additional orders nor genera.

If we take in the Atlantic United States, east of the Mississippi, and compare this area with Europe, we should find the species and the types increasing as we proceed southward, but about the same numerical proportion would hold.

But more interesting than this numerical preponderance—which is practically confined to the trees and shrubs—will be the extra-European types, which, intermixed with familiar Old World forms, give peculiar features to the North American flora—features discernible in Canada, but more and more prominent as we proceed southward. Still confining our survey to the Atlantic district, that is, without crossing the Mississippi, the following are among the notable points:—

(1) Leguminous trees of peculiar types. Europe abounds in Leguminous shrubs or under-shrubs, mostly of the Genisteous tribe, which is wanting in all North America, but has no Leguminous tree of more pretence than the Cercis and Laburnum. Our Atlantic forest is distinguished by a Cercis of its own, three species of Locust, two of them fine trees, and two Honey Locusts, the beautiful Cladrastis, and the stately Gymnocladus. Only the Cercis has any European relationship. For relatives of the others we must look to the Chino-Japanese region.

(2) The great development of the Ericaceæ (taking the order in its widest sense), along with the absence of the Ericeous tribe, that is, of the Heaths themselves. We possess on this side of the Mississippi 30 genera and not far from 90 species. All Europe has only 17 genera and barely 50 species. We have most of the actual European species, excepting their Rhododendrons and their Heaths,—and even the latter are represented by some scattered patches of Calluna, of which it may be still doubtful whether they are chance introductions or sparse and scanty survivals; and besides we have a wealth of peculiar genera and species. Among them the most notable in an ornamental point of view are the Rhododendrons, Azaleas, Kalmias, Andromedas, and Clethras; in botanical interest, the endemic Monotropeæ, of which there is only one species in Europe, but seven genera in North America, all but one absolutely peculiar; and, in edible as well as botanical interest, the unexampled development and diversification of the genus Vaccinium (along with the allied American type, Gaylussacia) will attract attention. It is interesting to note the rapid falling away of Ericaceæ westward in the valley of the Mississippi as the forest thins out.

(3) The wealth of this flora in Compositæ is a most obvious feature,—one especially prominent at this season of the year, when the open grounds are becoming golden with Solidago, and the earlier of the autumnal Asters are beginning to blossom. The Compositæ form the largest order of Phænogamous plants in all temperate floras of the northern hemisphere, are well up to the average in Europe, but are nowhere so numerous as in North America, where they form an eighth part of the whole. But the contrast between the Compositæ of Europe and Atlantic North America is striking. Europe runs to Thistles, to Inuloideæ, to Anthemideæ, and to Cichoriaceæ. It has very few Asters and only two Solidagoes, no Sunflowers, and hardly anything of that tribe. Our Atlantic flora surpasses all the world in Asters and Solidagoes, as also in Sunflowers and their various allies, is rich in Eupatoriaceæ, of which Europe has extremely few, and is well supplied with Vernoniaceæ and Helenioideæ of which she has none; but is scanty in all the groups that predominate in Europe. I may remark that if our larger and most troublesome genera, such as Solidago and Aster, were treated in our systematic works even in the way that Nyman has treated Hieracium in Europe, the species of these two genera (now numbering 78 and 124 respectively) would be at least doubled.

(4) Perhaps the most interesting contrast between the flora of Europe and that of the eastern border of North America is in the number of generic and even ordinal types here met with which are wholly absent from Europe. Possibly we may distinguish these into two sets of differing history. One will represent a tropical element, more or less transformed, which has probably acquired or been able to hold its position so far north in virtue of our high summer temperature. (In this whole survey the peninsula of Florida is left out of view, regarding its botany as essentially Bahaman and Cuban, with a certain admixture of northern elements.) To the first type I refer such trees and shrubs as Asimina, sole representative of the Anonaceæ out of the tropics, and reaching even to lat. 42°; Chrysobalanus, representing a tropical sub-order; Pinckneya, representing as far north as Georgia the Cinchoneous tribe; the Baccharis of our coast, reaching even to New England; Cyrilla and Cliftonia, the former actually West Indian; Bumelia, representing the tropical order Sapotaceæ; Bignonia and Tecoma of the Bignoniaceæ; Forestiera in Oleaceæ; Persea of the Laurineæ; and finally the Cactaceæ. Among the herbaceous plants of this set I will allude only to some of peculiar orders. Among them I reckon Sarracenia, of which the only extra-North American representative is tropical American, the Melastomaceæ, represented by Rhexia; Passiflora (our species being herbaceous), a few representatives of Loasaceæ and Turneraceæ, also of Hydrophyllaceæ: our two genera of Burmanniaceæ; three genera of Hæmodoraceæ; Tillandsia in Bromeliaceæ; two genera of Pontederiaceæ; two of Commelynaceæ; the outlying Mayaca and Xyris, and three genera of Eriocaulonaceæ. I do not forget that one of our species of Eriocaulon occurs on the west coast of Ireland and in Skye, wonderfully out of place, though on this side of the Atlantic it reaches Newfoundland. It may be a survival in the Old World; but it is more probably of chance introduction.

The other set of extra-European types, characteristic of the Atlantic North American flora, is very notable. According to a view which I have much and for a long while insisted on, it may be said to represent a certain portion of the once rather uniform flora of the Arctic and less boreal zone, from the late Tertiary down to the incoming of the Glacial period, and which, brought down to our lower latitudes by the gradual refrigeration, has been preserved here in Eastern North America and in the corresponding parts of Asia, but was lost to Europe. I need not recapitulate the evidence upon which this now generally accepted doctrine was founded; and to enumerate the plants which testify in its favour would amount to an enumeration of the greater part of the genera or subordinate groups of plants which distinguish our Atlantic flora from that of Europe. The evidence, in brief, is that the plants in question, or their moderately differentiated representatives, still co-exist in the flora of Eastern North America and that of the Chino-

Japanese region, the climates and conditions of which are very similar; and that the fossilised representatives of many of them have been brought to light in the late Tertiary deposits of the Arctic zone wherever explored. In mentioning some of the plants of this category I include the Magnolias, although there are no nearly identical species, but there is a seemingly identical Liriodendron in China, and the Schizandras and Illiciums are divided between the two floras; and I put into the list Menispermum, of which the only other species is Eastern Siberian, and is hardly distinguishable from ours. When you call to mind the series of wholly extra-European types which are identically or approximately represented in the Eastern North American and in the Eastern Asiatic temperate floras, such as Trautvetteria and Hydrastis in Ranunculaceæ; Caulophyllum, Diphylleia, Jeffersonia, and Podophyllum in Berberideæ; Brasenia and Nelumbium in Nymphæaceæ; Stylophorum in Papaveraceæ; Stuartia and Gordonia in Ternstromiaceæ; the equivalent species of Xanthoxylum, the equivalent and identical species of Vitis, and of the poisonous species of Rhus (one, if not both, of which you may meet with in every botanical excursion, and which it will be safer not to handle); the Horse-Chestnuts, here called Buckeyes; the Negundo, a peculiar offshoot of the Maple tribe: when you consider that almost every one of the peculiar Leguminous trees mentioned as characteristic of our flora is represented by a species in China or Manchuria or Japan, and so of some herbaceous Leguminosæ: when you remember that the peculiar small order of which Calycanthus is the principal type has its other representative in the same region; that the species of Philadelphus, of Hydrangea, of Itea, Astilbe, Hamamelis, Diervilla, Triosteum; Mitchella, which carpets the ground under evergreen woods; Chiogenes, creeping over the shaded bogs; Epigæa, choicest woodland flower of early spring; Elliottia; Shortia (the curious history of which I need not rehearse); Styrax of cognate species; Nyssa, the Asiatic representatives of which affect a warmer region; Gelsemium, which, under the name of Jessamine, is the vernal pride of the Southern Atlantic States: Pyrularia and Buckleya, peculiar Santalaceous shrubs; Sassafras and Benzoins of the Laurel family; Planera and Maclura; Pachysandra of the Box tribe; the great development of the Juglandaceæ (of which the sole representative in Europe probably was brought by man into South-Eastern Europe in prehistoric times); our Hemlock-Spruces, Arbor-Vitæ, Chamæcyparis, Taxodium, and Torreya, with their East Asian counterparts, the Roxburghiaceæ, represented by Croomia—and I might much further extend and particularise the enumeration—you will have enough to make it clear that the peculiarities of the one flora are the peculiarities of the other, and that the two are in striking contrast with the flora of Europe.

(*To be continued.*)

SOCIETIES AND ACADEMIES

London

Linnean Society, December 18, 1884.—Sir John Lubbock, Bart., F.R.S., President, in the chair.—The following gentlemen were elected Fellows of the Society:—Liet.-Col. W. R. Lewis, and Messrs. T. B. Blow, H. G. Greenish, A. G. Howard, L. de Niceville, C. B. Plowright, and F. Shrivell.—Mr. H. Ling Roth showed roots of sugar-cane grown in Queensland; the plant appearing to him to possess two sorts, viz. ordinary matted fibrous roots and others of a special kind.—Mr. E. Alf. Heath exhibited a wild cat found dead in a trap in Ben-Armin Deer Forest, Sutherlandshire, where they are still frequently met with.—Mr. W. H. Beeby called attention to examples of burreed (*Sparganium*) obtained at Albury Ponds, Surrey, the plant being quite distinct from the other British species; he proposed for it the name of *S. neglectum.*—In illustration of ornithological notes, Mr. Thos. E. Gunn showed an interesting series in varied plumage of the somewhat rare British bird, the blue-throated warbler. The examples in question were procured by Mr. G. E. Power at Cley, on the Norfolk coast, in September, 1884. Mr. Gunn also exhibited an immature female little bittern, shot at Broxbourne Bridge, Herts, on October 15 in the same year; as likewise a hybrid between a goldfinch and bullfinch, which possessed the marked characteristics of both parents.—Attention was drawn to Mr. R. Morton Middleton's examples of varieties of Indian corn (*Zea mays*, L.) from the United States, Natal, and the borders of the River Danube. The specimens showed marked differences from each other in size, colour, form, and in ornamentation of the seeds.—Mr. Thiselton Dyer exhibited life-size photographs of cones of two species of *Encephalartus* from South Africa, viz. *E. longifolius* and *E. latifrons*, neither hitherto figured in European books. He also showed tubers of *Ullucus tuberosus* from Venezuela, which, though esteemed as an esculent in South America, proved inedible when grown at Kew.—A paper was read by Mr. Henry O. Forbes, on contrivances for insuring self-fertilisation in some tropical orchids. The author described in detail the structural peculiarities of certain Orchidaceæ which had been made the subject of study by him under favourable circumstances. He arrives at the conclusion that a number of orchids are not fertilised by insects, but are so constructed as to enable them to fertilise themselves. This paper was illustrated by diagrams referring more particularly to such forms as *Phajus Blumei*, *Spathoglottis plicata*, *Arundina speciosa*, *Eria javensis*, and others.—Prof. St. G. Mivart read a paper on the cerebral convolutions of the Carnivora and Pinnipedia, and wherein were described for the first time in detail the brains of *Nandinia*, *Galidia*, *Cryptoprocta*, *Bassaricyon* (from a cast of the skull), *Mellivora*, *Galictis*, and *Grisonia*. The author, confirming the views of previous observers, gave additional reasons for a three-fold division of the Carnivora into Cynoidea, Æluroidea, and Arctoidea, though he remarked that amongst the Æluroids the section of Viverrina formed a very distinct group, judged by the cerebral characters. He specially called attention to the universal tendency amongst the Arctoidea to the definition of a distinct and conspicuous lozenge-shaped patch of brain substance defined by the crucial and precrucial sulci. This condition, which he found in no single non-arctoid Carnivora, he also found in the brain of *Otaria Gillespii*, and afterwards in *Phoca vitulina*, where it is very small and much hidden. This fact he adduced as an important argument in favour of the view that the Pinnipedia were evolved from some Arctoid, probably Ursine, form of land Carnivora.—Mr. F. O. Bower read a paper on apospory in ferns. His microscopical investigations on the growth of sporophore generation to the prothallus without the intervention of spores but confirms the statements of Mr. Chas. T. Druery on *Athyrium Filixfœmina*, var. *clarissima*, previously communicated to the Society. Mr. Bower, moreover, finds the case in point to hold good in certain other ferns, for example, *Polystichum angulare*, where there is the formation of an expansion of *undoubted prothalloid nature* bearing sexual organs by a process of purely vegetative outgrowth from the fern plant. That is, there is a transition from the sporophore generation to the oosphore by a vegetable growth, and without any connection either with spores or indeed with sporangia or sori. The author goes on to point out the bearing of these observations and cultures on the general life history of the fern, so far as the modifications of the genetic cycle are concerned; and he further compares this new phenomenon of "apospory" in ferns with similar cases in other plants, while insisting on the importance of the cases at issue.—A communication on the aërial and submerged leaves of *Ranunculus lingua*, L., was read by Mr. Freeman Roper. He shows from specimens obtained near Eastbourne that the two sets of leaves in question differ so materially from each other that they might not be suspected to belong to the same plant, the submerged being larger, broader, ovate or cordate, and possessing abundance of stomata.

Geological Society, December 14, 1884.—W. Carruthers, F.R.S., Vice-President, in the chair.—David Llewellin Evans was elected a Fellow of the Society.—The following communications were read:—On the south-western extension of the Clifton fault, by Prof. C. Lloyd Morgan, F.G.S., Assoc. R.S.M.—On the recent discovery of Pteraspidian fish in the Upper Silurian rocks of North America, by Prof. E. W. Claypole, B.A., B.Sc. Lond., F.G.S.—On some West-Indian phosphate deposits, by George Hughes, F.C.S. (Communicated by W. T. Blanford, LL.D., F.R.S., Sec.G.S.).—Notes on species of *Phyllopora* and *Thamniscus* from the Lower Silurian rocks near Welshpool, Wales, by George Robert Vine (Communicated by Prof. P. Martin Duncan, F.R.S., F.G.S.).

Victoria (Philosophical) Institute, January 5.—A paper on "The Religion of the Aboriginal Tribes of India," by Prof. Avery, was read. In it the author sketched the peculiarities of the beliefs of those tribes, so far as was known.

Sydney

Royal Society of New South Wales, November 5, 1884.—H. C. Russell, B.A., F.R.A.S., President, in the chair.—Five

new members were elected and 129 donations received. A paper was read, "Notes on some mineral localities in the northern districts of New South Wales," by D. A. Porter. The following extracts from a letter, dated from Queensland, October 8, to Prof. Liversidge, from Mr. Caldwell, were read:—"Ceratodus has interfered with Platypus. The Platypus eggs were hatched three weeks ago, and I should have been in New England by now, but Ceratodus is much more important. Platypus embryos are quite easy to get. I can't understand how they have not been got before. The fact tha the monotremes are oviparous is the end of the research for many. They don't understand that it is the fact of the egg having a lot of yelk that promises to yield valuable information. Here are some of the principal points in the development of Ceratodus as observed on the whole embryos. I have not attempted to make sections yet; you know what section-cutting is now-a-days. The egg measures about 2½ mm. diameter, and has the protoplasmic pole darker, as in Amphibia. This egg is surrounded by a strong, closely-investing gelatinous membrane about 3½ mm. thick. The segmentation is complete (Holoblastic). Part of the blastopore remains open, and persists as anus. The stages up to hatching closely resemble those of the newt, Amblystoma. After hatching, the larva goes into the mud. It lies on its side like Pleuronectidæ among Teleosteans, and the oldest stages I have reared still show no signs of external gills. The larval changes I expect will continue for many weeks, and I have two plans to save my waiting here, both of which I intend to put into execution at once. First, I shall leave an aquarium with a large number of the larvæ here on a station, where a friend has kindly promised to put a few of the fish in a bottle every day. Second, I shall bring a supply of eggs to Sydney, and attempt to rear them in my laboratory. I hope to get to Sydney in about a fortnight or three weeks time. I have more than thirty blacks with me now; they have found over 500 Echidna in the last six weeks."—Prof. Liversidge exhibited specimens of sapphires, zircons, the topaz and diamond from the old gold workings near Mittagong, and stated that flints occurred at these mines closely resembling those of the cretaceous formations at home.—Mr. C. S. Wilkinson exhibited specimens of chloride of silver from Silverton, native antimony in calcite, Lucknow, also dendritic gold and arsenical pyrites in massive serpentine.—Mr. Charles Moore announced the discovery of a new species of the giant Australian lily, between the Clarence and Richmond Rivers, and promised some notes upon it at the next meeting.

PARIS

Academy of Sciences, December 29, 1884.—M. Rolland, President, in the chair.—Note on the classification of the moles (genus *Talpa*, L.) of the old world, by M. Alph. Milne-Edwards.—Theorem regarding the complete algebraic polynomes; its application to the rule of Descartes' signs, by M. de Jonquières.—On the integers of total differentials, by M. H. Poincaré.—On the integers of total differentials, and on a class of algebraic surfaces, by M. E. Picard.—On a series analogous to that of Lagrange, by M. Amigues.—Some simple and closely related formulas for the equilibrious pressure of sandy masses or bodies without cohesion, by M. Flamant.—Rectification of the numerical results indicated in a previous communication for the calculation of compressed gas manometers, by M. E. H. Amagat. The rectifications here made are stated by the author in no way to affect his general conclusions.—On seleno-uria and the substances derived from it, by M. A. Verneuil.—On the solubility of the substances comprised in the oxalic series—

$$CO(OH)—(CH^2)^n—CO(OH),$$

by M. Friedel.—On the composition of the seed of the cotton-tree and on the abundance of alimentary substances contained in this grain, by M. Sacc. Writing from Cochabamba under the date of October 25, 1884, the author announces the discovery of a new alimentary substance presenting some most remarkable features in its composition. The accompanying analysis shows that this seed of the cotton-tree, of which several varieties are cultivated in Bolivia, is the richest of all known grains in nitrogenous substances. When milled, it yields the following results:—

Yellow meal	56·50 kilogrammes
Black bran	40·50 ,,
Waste	3·00 ,,
	100 ,,

The writer is convinced that this flour is destined to take an important place in human alimentation, and in the preparation of all kinds of pastes, where it may act as a substitute for milk.—Note on the history of the discovery of the action of the white globules of the blood in inflammatory complaints, by M. A. Horvath. This discovery, hitherto attributed to Cohnheim, is here assigned to Dutrochet, who, so far back as 1824, accurately described the migration of the sanguine globules and their passage into the organic tissues.—Note on the biological evolution of the genus Aphis, and of the allied genera in the family of the Aphidæ, by M. Lichtenstein.—On the discovery of the impression of an insect in the Silurian sandstones of Jurques, Calvados, by M. Ch. Brougniart. The traces are described of the wing of a blattina, to which the author gives the name of *Palæoblattina douvillei*, in honour of M. Douvillé of the Paris School ol Mines.—On a crystalliferous vitreous mass resembling obsidian, and evidently derived by igneous action from the schistose rocks of the Commentry coal-measures, by M. Stanislas Meunier.

STOCKHOLM

Royal Academy of Sciences, December 10, 1884.—Prof. Edlund communicated some observations made during the last years confirming his theory on the origin of the electricity of the air, and also of the origin of the aurora borealis and of thunderstorms.—Prof. Nordenskjöld presented a paper on kryokonite from the inland ice of Greenland by himself.—Prof. Ångström gave an account of a report by E. D. Norrman, civil engineer, concerning his observations on ship-building, &c., during a Continental tour undertaken with a grant given by the Academy from the funds of the Litterstedt donations.—Dr. Widman reported on his own researches on a new sort of indigo and on some new derivations of chinolin produced by him from kumminol. The Secretary, Prof. Lindhagen, presented the following papers:—On the passage of the light through isotropical substances, by Prof. Rubenson.—A method to separate chlorine and bromine quantitatively, by Dr. E. Berglund.—On Vortmann's method to determinate chlorine directly, and also the presence of bromine, by the same.—On the intermediate orbit of the comet of Faye in the vicinity of Jupiter in the year 1841, by Dr. Alexander Shdanow of Pulkowa.

THE EARTHQUAKES IN SPAIN

EVEN the most conservative believer in the stability of Mother Earth must by this time have had his faith sorely shaken. Year after year, and month after month, we receive tidings of more or less serious shakings, varying from slight movements, such as merely set bells ringing and disturb the crockery on kitchen-shelves, to such shocks as convulse wide districts and bring with them disaster to life and limb as well as destruction to property. As if these tangible proofs of insecurity were not enough, we have learnt further that what we have been in the habit of dignifying with the name of the "solid" earth is really in a state of perpetual tremor. The thud of falling rain-drops, the patter of birds' feet, the tread of cattle, the gambols of children, so affect the ground on which we walk that the vibrations which they cause in it can be made clearly audible by the microphone and visible by the galvanometer. The position of the sun in the sky, the rise and fall of the tides, the thermometrical and barometrical oscillations of the atmosphere, produce in the outer parts of the earth corresponding pulsations, which, though not always certainly referable to their originating source, are perfectly recognisable, and can be registered by sufficiently delicate instruments. So that, instead of being on the whole a motionless, inert mass, the land is, in its way, almost as restless as the sea.

Fortunately, we are not sensible of these daily and hourly vibrations. It is only from time to time, by the news of earthquake-shocks from different quarters of the globe, that our attention is vividly drawn to the subject, and we are made to realise how little right we have to count on the continued stability of our own district. The daily tidings from the south of Spain, coming after so many recent chronicles of earthquake disaster in Europe, cannot but recall our thoughts to this subject. When the peace and goodwill of Christmas-tide were once more brightening the close of the year all over Christendom, the inhabitants of a wide tract of Andalusia were suddenly thrown into consternation by a succession of powerful earthquakes. The district most severely visited lies in the province of Granada and Malaga, and forms a parallelogram measuring about 70 miles from east to west and about 35 from north to south. The eastern part of the affected district passes into the great range of the Sierra Nevada, of which the highest peaks rise between 11,000 and 12,000 feet above the sea. Westwards, this range throws off some minor spurs, particularly the Sierras Tejada and Alhama, which curve round towards the north-west. The chief mass of the Sierras consists of crystalline schists stretching east and west, and flanked with Tertiary strata, from beneath which various Jurassic and other Secondary rocks emerge. The area of maximum destruction appears to be among the Western Sierras, and on the ground to the south and north of them.

The greatest amount of damage has been done at Alhama, which is almost entirely ruined. This little town stands nearly on the junction of the Tertiary rocks with the schists that rise into the more rugged ground of the mountains. A little to the south-east Abunuelas has also suffered severely. From that central area the shocks seem to have lessened outwards, but to have been felt most along the northern and southern flanks of the Sierras. According to one account the shocks have indicated earth-waves from south to north, with return movements in the contrary direction. Not improbably the actual focus of disturbance lies along the axis of the Sierras Alhama and Tejada. But the shocks have been felt over a much wider area. They have extended along the line of the mountains at least as far as Gibraltar in the west, though they are not recorded as having been marked in an easterly direction. Northwards, the towns and villages lying nearest to the centre of commotion have suffered most—Antequera, Loja, Granada. But far beyond these districts, terror was occasioned to the people of Cordova, Cadiz, and Seville, and the first shock was felt even at Madrid. No sea-wave has been chronicled as having affected any part of the coast, whence we may reasonably conclude that the earthquakes have not originated under the sea.

The Spanish peninsula has long had an evil reputation for the frequency, destructiveness, and long continuance of its earthquakes. In the present case the shocks are said to have begun three days before Christmas; but the first destructive wave arose on Christmas day. Since that date there has been an almost daily continuance of shocks of varying intensity. Such was also the case in the summer of 1863 along the great range of Sierras from Malaga to Alicante, and still earlier, in 1849, the same district continued to vibrate for several months.

Unfortunately, no accurate registers have been kept of these earth-tremors. Observations on earthquake phenomena made after the event, though useful so far, are now recognised as altogether insufficient to enable us to solve the problems presented by this interesting, but difficult, branch of geological physics. The establishment of self-registering apparatus, which was temporarily assisted many years ago by the British Association in the case of the simple instruments set up at Comrie in Perthshire, and which, more perfectly developed in Italy, has recently been so well inaugurated in Japan by Profs. Milne and Ewing, is the only satisfactory method of accumulating the necessary data. Until facts thus chronicled have been patiently gathered for some years in regions widely separated from each other, alike in distance and in geological structure, seismology must be content to remain very much at a stand. Of course, speculation will be as rife as ever, but cautious men of science will probably withhold their judgment until they are in possession of data of a kind that has not yet been systematically observed and registered.

But even before these data are gathered for the region of Andalusia, we can hardly doubt that fundamentally the shocks so often felt there arise from the process of mountain-making. The vibrations are propagated along the Sierras, and are felt with most violence near their flanks. They are probably in some way connected with the movements of the terrestrial crust that first started and have successively upraised the long parallel lines of mountainous ridge that diversify the surface of the Spanish tableland. Among the questions

awaiting investigation is whether any perceptible effect on the height and form of a mountain chain can be detected after its flanks have been convulsed with earthquakes; whether its rocks have been more tilted or folded or fractured. Men are usually too overwhelmed by the losses to life and property to take heed of such matters as these, and it may seem almost cold-blooded to suggest them for practical consideration. In all mountain districts much subject to earthquakes, it would be desirable to have an accurate system of levelling carried out, so that after a time of disturbance the heights could be checked. It would also be useful to have numerous photographs of cliffs and other sections where the rocks are well exposed, and where, therefore, any change of inclination, even to a slight extent, could be ascertained and measured. In regions where, as in the Karst, the earthquakes probably arise from the giving way of the roofs of underground tunnels or caverns, likewise in volcanic districts, the precautions here suggested might be of little use. But in those tracts where mountain-making is probably still in progress, they might supply us with many suggestive facts.

There is one other feature in the present Andalusian earthquakes to which allusion should be made. It has often been asserted and often denied that the occurrence of earthquakes is connected with the state of the atmosphere at the time. There certainly seems no doubt that in Europe, at least, the crust of the earth is considerably more convulsed by earthquakes in winter than in summer. When the shock of December 25th struck terror into the provinces of Malaga and Granada, the barometer, which a fortnight before had been remarkably steady, was exceptionally low and variable. Mr. George Higgin, of Broadway Chambers, Westminster, sends us an extract from a letter received by him from one of his engineers at Albox, in the valley of the River Almanzora, province of Almeria, not far to the eastward of the scene of disturbance. The writer, who was still unaware that there had been any earthquake, states that after December 19th a severe gale sprang up, lasting four days; the barometer varied from 29·28 on December 19th to 28·52 on the 27th, and continued to oscillate to such an extent that no trustworthy levellings could be made with it. A correspondent of the *Times*, writing on Sunday last, also mentions the low state of the barometer, and that the severest and greatest number of shocks continues to be felt from 5 p.m. till 5 a.m., and that since the outset, at intervals of about a week, the movement has shown a recrudescence with each return.

There has been also the usual chronicle of secondary effects from the earthquake shocks. Landslips have occurred, with the consequent disturbance of drainage. In one place a village has slid northwards about sixty feet, leaving a deep semicircular crevasse where it previously stood. The displaced ground has intercepted the course of an adjacent stream, so that a lake is forming behind the obstruction. At Periana a mass of rock and earth, disengaged from the slopes above, is said to have demolished a church and 750 houses. Among the numerous sulphur-springs of the region there has been considerable disturbance. Some of these sources, as has often been observed at Vesuvius and elsewhere, disappeared after the first shock, but in a day or two afterwards began to flow again at a higher temperature than before.

THE STABILITY OF SHIPS

A Treatise on the Stability of Ships. By Sir E. J. Reed, K.C.B., F.R.S., M.P. (London: C. Griffin and Co., 1885.)

THE stability of ships is a subject that has attracted considerable attention of late. Many disasters have happened to ships through insufficient stability, and have caused scientific men as well as practical naval architects to apply themselves to a renewed and close investigation of the subject. The result is that the ideas which till late prevailed respecting it are seen to be often superficial and incomplete, and in some cases not entirely free from error.

Sir Edward Reed has done good service in bringing out a treatise upon stability which presents the matter in a fresh, readable, and instructive form. Singularly enough this is the only work in the English language which attempts to deal exhaustively with it. Notwithstanding the magnitude and complexity of the subject, and its vast importance to all who are responsible for the wise design and safe management of ships, its treatment has previously been of a very restricted and imperfect character. The student of naval science has required to consult works which range over the wide field of naval architecture, and numerous papers that lie entombed in the published proceedings of learned societies, in order to acquire anything approaching a comprehensive knowledge of the problem of stability. Sir Edward Reed has brought together and placed into relation to each other the investigations made at various times by eminent men of the science of the subject, and the practical developments which have resulted therefrom. Among these are included the researches of French mathematicians and naval constructors, which have hitherto been but little known in this country.

The statement that a floating body, such as a ship, when laden so as to float at a given draught of water may assume any position—upright, inclined, or upside down—or it may when floating upright and in equilibrium be capsized with ease or with difficulty, according to the character or degree of the stability it may possess is the veriest scientific truism. Many may suppose it to be unnecessary, in this shipbuilding country, to make so self-evident an observation. Yet trite and obvious as it may appear when put into this form, it has been strangely, almost culpably, ignored by many who are responsible for the safety of ships. Very few exact investigations of the stability of individual ships have been made till quite recently; and even those that were attempted have frequently been imperfect and inconclusive.

The correct principles upon which the stability of ships depends were not demonstrated till the middle of the last century. Bouguer explained the properties of the metacentre in 1746, and gave a formula by which its position may be calculated. He also showed how the initial stiffness, and height of centre of gravity, of a ship may be determined by a practical experiment; this being the method of inclining vessels which is at length becoming usual in this country. Bouguer's investigations were followed up and extended by D. Bernouilli and Euler; and it was shown how the righting moments at large angles of inclination from the upright may be determined.

Atwood brought forward the subject clearly and forcibly

and at considerable length, in two papers read before the Royal Society in 1796 and 1798. He laid down the fundamental formula by which the length of the arm of the righting or upsetting couple may be determined for any angle of inclination of a ship; and he showed how the several terms contained in it may be calculated. Two of these terms, viz. the volumes of the wedges of immersion and emersion, and the positions of their centres of gravity, involved very lengthy and complicated calculations. The tediousness and complexity of stability investigations have been chiefly caused by the difficulties connected with finding by actual measurement and calculation the solid contents of these wedges and the positions of their centre of gravity.

Let Fig. 1 represent the transverse section of a ship, of which W L is the line in which the plane of flotation, when the ship is upright, is cut by the plane of the paper; the centre of gravity of the whole ship being at G. Let B similarly represent the centre of gravity of the volume of the ship's displacement, or centre of buoyancy, as it is commonly called. Now, suppose the ship to be inclined a few degrees by some external force that acts horizontally, and therefore does not alter the displacement; and let

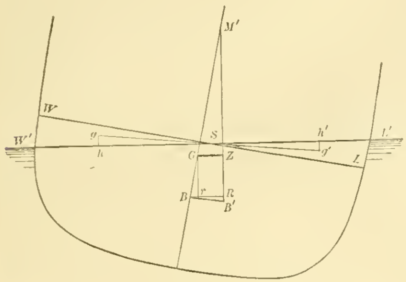

Fig. 1.

W' L' represent the new water-line. The effect of the inclination has obviously been to lift out of the water a wedge-shaped body, of which W S W' is the section, and to submerge on the opposite side of the ship another somewhat similar wedge-shaped body, of which the section is L S L'. These wedges are known as the wedges of immersion and emersion respectively. They are each bounded on the outside by the outside form of the ship, and will therefore usually differ in external form; but they must be precisely equal in volume, or otherwise the whole displacement of the ship could not remain unaltered.

The inclination of the ship through the angle W S W' has changed the position of the centre of buoyancy B to B'; and G Z is the length of the perpendicular let fall from G, the centre of gravity, upon the vertical B' M, through B'. G Z is the arm of the couple at the ends of which the weight of the ship and the upward pressure of the water act; and it is commonly called the righting arm. Atwood's fundamental formula for determining the length of the righting arm is—

$$GZ = v \times hh'/V - BG \sin \theta,$$

v being the volume of either of the wedges W S W', L' S L; $h\,h'$ the distance, measured parallel to W' L', between g and g', the centres of gravity of these wedges; V the volume of the ship's displacement; and θ the angle of inclination W S W'.

It is obvious that the labour of calculating the volumes and positions of centres of gravity of such irregularly shaped bodies as the wedges of immersion and emersion must be very great. The labour and difficulty are further increased by the necessity of drawing the inclined water lines, such as W' L', in positions which give equal volumes for these wedges. The point S, where the inclined water-line intersects the upright water-line, thus requires to be determined separately for each angle of inclination. Atwood's manner of approximating to the volumes and moments of these wedges was simplified by Mr. S. Read. The method which has commonly been adopted in recent years is, however, one brought forward at the Institution of Naval Architects, by Mr. F. K. Barnes, in 1861.

The old systems of stability calculation, even as modified by Mr. Barnes, were so excessively laborious and complex, that very few attempts were ever made to apply them to ships. The initial stiffness, as determined by the metacentric height, was practically the only element of stability that was investigated. It appears that, prior to 1867, no calculations were made which showed how the stability of a ship became affected by inclining her till the water-line came up over the deck, or at what angle the stability vanished. This was done for the first time at the Admiralty in 1867 by Mr. William John, under the direction of the author of the present work. The results of these investigations were published by Sir E. J. Reed in an interesting and instructive paper upon "The Stability of Monitors under Canvas," read before the Institution of Naval Architects in 1868. Curves are appended to this paper which show how the righting moments vary at successive angles of inclination, and the point at which they vanish. This paper proved conclusively how great are the dangers that have to be guarded against in ships of low freeboard and with high centres of gravity.

The extended application of stability calculations to cases involving greater irregularities in the volumes of the wedges of immersion and emersion than are contemplated by Atwood—such, for instance, as are caused by deck edges becoming immersed, or portions of deck erections becoming included in the volumes of the immersed wedges—created a demand for still more systematic and simple modes of calculation. This was supplied by Messrs. White and John in a paper read before the Institution of Naval Architects in 1871.

Down to the time of the *Daphne* disaster, which occurred in July, 1883, stability calculations made no further progress of importance in this country. At the Admiralty, and in some of our mercantile shipyards, the processes above described were gone through in cases where full knowledge of a ship's stability was considered requisite. Such calculations often took about a month to complete; and the results obtained were usually limited to a knowledge of how a ship's righting moment varied with angle of inclination at one or more chosen draughts of water. Even this was not considered essential when very light draughts of water were being dealt with.

The evidence given at the *Daphne* inquiry, and the

report of the Government Commissioner, Sir E. J. Reed, directed attention to imperfections in this department of shipbuilding practice, and furnished a powerful stimulus to renewed inquiry. Valuable results were speedily forthcoming in the shape of more complete and general expositions of the theory of stability than had previously been given: and in a great simplification, which at the same time included an extension, of the system of calculation. One of the most useful portions of the present work is that which describes the improvements thus made in the theory and practice of the subject.

The modern improvement of the theory is shown by Sir E. J. Reed to be in the direction of considering the variation of stability with draught of water, and the amount of stability a ship will possess at light draughts. The *Daphne* inquiry showed that the danger of instability which is sometimes to be found associated with light draught of water was frequently lost sight of because of a prevailing belief that, so long as a vessel has a high side out of water, and any initial stiffness, she will have a large range of stability. This point is clearly and fully dealt with by Sir E. J. Reed in his present work; and he states a general proposition which underlies it, and which was first enunciated by Prof. Elgar in the *Times* of September 1, 1883. It is that, if any homogeneous body which is symmetrical about the three principal axes at its centre of gravity be of such density as to float in equilibrium with its lowest point at a depth x below the water, then if the density be altered so as to make it float with its highest point at a height x above the water, the righting moments will be the same in both cases at equal angles of inclination, and, consequently, the range of stability and complete curves of righting moments will be the same. Sir E. J. Reed also gives copious extracts and diagrams from a paper read by Prof. Elgar before the Royal Society in March last, in which the variation of righting moment with draught of water is shown not only for symmetrical bodies, but also for floating bodies of irregular form and for an actual ship. These investigations indicate that the effect of lightness of draught upon stability may be as prejudicial, or even more so, than that due to low freeboard.

Sir Edward Reed deals very fully with the recent practical developments of the subject, and with the improved systems of calculation that have been devised. These have for their primary object the direct construction of curves showing the variation of righting arm with draught of water at fixed angles of inclination. The wedges of immersion and emersion are no longer dealt with in the stability calculations. Atwood's formula involving the volumes and moments of the wedges of immersion and emersion is discarded, and the following one is employed (see Fig. 1) $GZ = BR - BG \sin\theta$. BR is computed by calculating the under-water volume at the inclined water-line W′L′, and its statical moment. These calculations can be made very quickly and easily with the aid of Amsler's mechanical integrator: and the complication involved by dealing with the two separate wedges, and equating their volumes, may thus be avoided. Sir Edward Reed describes the methods put forward by Mr. W. Denny—who appears to have been the first to suggest this important step—Mr. Macfarlane Gray, Mr. Benjamin, and others.

It is singular that while naval architects in this country were thus working out for themselves those extensions of the difficult problem of stability which modern requirements have demanded with continuously increasing force, the French appear to have been long in possession of a complete and admirable system. So long ago as 1863 M. G. Dargnies was making calculations of stability at Marseilles for numerous angles of inclination, and for four or five draughts of water; and in 1864 M. Reech put forward a most ingenious and perfect method for bringing all the probable stability conditions of a ship into full view and under calculation. The advantages of this method were so striking that it was not long in becoming practically adopted in France, and, in 1870, M. Risbec prepared a paper upon it, together with a calculation form for facilitating its application. Sir Edward Reed gives a concise and clear exposition of the systems of MM. Dargnies, Reech, and Risbec, together with an example of M. Risbec's calculation form. The investigations of MM. Ferranty and Daymard are also described in detail. The latter are probably better known in this country than any of the others referred to, in consequence of a paper which M. Daymard read upon the subject before the Institution of Naval Architects in April last.

There is much in this large and important work to which it is hardly possible to refer, still less attempt an adequate discussion of, within the limits of a short review. We shall return to the subject in a future number. In the meantime, all who are interested in this branch of science, and its bearing upon the construction and safe treatment of ships, will do well to refer to the book itself for full and precise information upon the various aspects of the theory of stability and its practical applications. Fundamental principles are clearly described and illustrated, and may be readily understood by persons possessing an elementary knowledge of mathematics. On the other hand, the elegant and extensive investigations of Dupin, Leclert, Guyon, Moseley, Woolley, and others furnish profitable subjects of study for the most advanced of mathematicians.

(To be continued.)

OUR BOOK SHELF

Natural History Sketches among the Carnivora, Wild and Domesticated; with Observations on their Habits and Mental Faculties. By Arthur Nicols, F.G.S., &c. (London: L. Upcott Gill, 1885.)

THIS little volume of some 250 pages is full of interest: treating somewhat of lions and tigers, it has a pleasant portion of a chapter about cats, but the bulk of the volume is devoted to man's faithful friend, the dog. Of the several excellent illustrations we would especially mention the life-like one of a lioness watching its prey, from a drawing by Mr. J. T. Nettleship, which is very full of vigour and muscular force, one of the black-maned African lion, by Mr. C. E. Brittain, and one of Chang, Mr. G. B. Du Maurier's Grand St. Bernard, by Mr. T. W. Wood. As one of the interesting subjects touched on by Mr. Nicols, we may allude to that treating of the sense of smell in dogs. He alludes to this in connection with the habit possessed by some dogs of rolling in decaying animal, or even vegetable, substances. On one occasion Mr. Nicols noticed his retriever vigorously anointing himself by rolling about in a clump of living fungi which emitted a particularly evil smell. This is thought to be an inherited habit, or, as Mr. H. Dalziel writes, "Taste and smell being

closely allied senses, this rolling causes pleasurable sensations from association with the glorious feasts enjoyed on battle-fields and on putrid carcases of animals," and from this the author hints that possibly, and even probably, when grouse or venison come to our tables in a state of actual decomposition, this represents a taste acquired years ago by the conditions of a primitive life, and is not to be distinguished from a habit which brings upon our domestic dogs the severest reprobation and prompt chastisement. It seems a subject, however unsavoury, well worthy of being investigated, and doubtless many facts bearing on it in reference to uncivilised people are yet to be narrated. Once we call to mind a small knot of semi-civilised Africans captured in a slave dhow off Mosambique that we interrupted at a midnight feast; they were partly eating and partly smelling a mass of half-putrid fish, which seemed, to say the least, to make them uproarious. They had been under civilisation of a sort since their infant days, but seemed full of hereditary instincts. Mr. Nicols's work is full of his own careful observations, and forms a most pleasant addition to our knowledge of the habits and mental faculties of the Carnivora.

Entwickelung der Ortschaften im Thüringerwald. Von Dr. F. Regel. *Petermann's Mitteilungen*, Ergänzungsheft No. 76. (Gotha: Perthes, 1885.)

THIS is a very complete account of the origin and development of the towns and villages in the region known as "the Thuringian Forest," with a special chapter on the geology, topography, and climatology of the district, and a valuable map. The "Thuringian Forest" extends from Eisenach, on the north-west, to Schleusingen, on the south-east, and covers an area of about 1200 kilometres, with a population of 143,986. The mountains of this region are mainly composed of granite, gneiss, palæozoic strata, and porphyry. About a third of the district is still covered with wood. Formerly there was a great variety of trees, comprising the pine, oak, beech, birch, elder, maple, aspen, and willow; but now the forests consist almost entirely of pines, with a few beech woods between Friederichroda and the mediæval walled town of Schmalkalden. The average temperature is somewhat lower than that of the whole of Germany. In the higher villages neither wheat nor the finer kinds of fruit will thrive, and there is frost during from ten to eleven months in the year. The climate, however, is very healthy, and the beauty of the scenery and purity of the mountain streams attract many visitors during the summer months. The highest, and one of the most popular, of these summer resorts is Oberhof, a village at the top of the pass over the Schützenberg, of which the earliest record is in the year 1267. Only oats and potatoes can be grown here (2541 feet above the sea-level), and even the house-sparrow cannot be acclimatised. Eisenach, the capital of the district, is chiefly known on account of the confinement of Luther in the neighbouring castle of Wartburg, which was erected to guard the Thuringian frontier on the west in the years 1067 to 1070. This fortress was close to the junction of two important roads from Erfurt and Mühlhausen, and, as usual in such cases, a town rapidly grew up at the foot of the hill on which the fortress was built. Eisenach now has 13,000 inhabitants, with three churches and several factories. Other towns and villages not so favourably situated owed their development to the neighbourhood of mines, healing waters, &c. Ruhla, a flourishing town of 4500 inhabitants, was celebrated in the first half of the sixteenth century for its steel manufactures, but foreign competition and heavy taxes nearly ruined the place, and in 1748 the population had considerably diminished. The enterprising spirit of the inhabitants, however, was soon drawn into a new channel by the discovery of mineral waters and the introduction of the manufacture of carved amber and pipe-bowls of imitation meerschaum, an industry which has attained considerable proportions. A somewhat similar history is that of the manufacturing town of Ilmenau, which is first mentioned in the chronicles of the fourteenth century. It flourished as an important centre of the copper-mining district of the Ilm up to the year 1739, when the mines were flooded by an inundation. In 1752 the town was burnt to the ground, and, though partly rebuilt, it shared in the general distress caused by the seven years' war, and did not revive until the beginning of the present century, when the manufacture of glass, porcelain, and toys was introduced. In 1838 the establishment of a hydropathic institution afforded a further stimulus to the trade of Ilmenau, and the population has increased from 1972 in 1809 to 4593 in 1880. On these and other places of less note in the Thuringian Forest Dr. Regel's work affords abundant information, though it is somewhat overcharged with notes and references which serve rather to display the extent of the author's reading than to illustrate his text.

LETTERS TO THE EDITOR

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

River Thames—Abnormal High Tides

REVERTING to my letter of December 19, 1883, inserted in NATURE for January 10, 1884, I append an abstract of salient exceptional tides of last year similar to that accompanying my former letter, from which it will be seen that the maximum elevation of tide is eleven inches less than in 1883, and the excess over the computed rise is also less by seventeen inches than in 1883—in each year resultant on north-north-west gales. Both year's results may be said to be analogous, and each showing how sensitive is the high-water level and how easily it is affected and raised by a change from south and west to northerly winds.

J. B. REDMAN

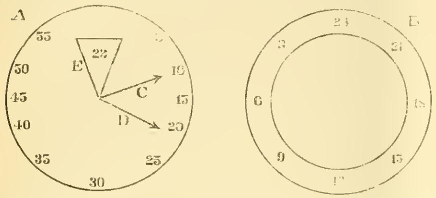
6, Queen Anne's Gate, Westminster, S.W., January 5

Our Future Clocks and Watches

IT is to be hoped that the absurd dial of which you give a drawing will not come into general use. Why not adopt the convenient shape which for more than a century has been in use

[1] Wind Influence. [2] Northerly Influence.
[3] Still felt. [4] Wind blowing right up the estuary.
[5] Sewage up to Westminster with this tide. [6] N.N.W. day before.
[7] Maximum tide of year; W.N.W. gale day before.
[8] Gale and remarkable fall of barometer = 29° 10′.

on the continent for some jewelled watches?:—A is the shape of the visible dial; C is the minute hand; D is the second-hand (sometimes dispensed with); E is an aperture in the dial through which is seen the hour, brought there by the hourly revolution of the wheel B; B is a wheel (and in watches of the size of a



shilling a series of wheels or a metallic band rolling round a drum of special construction for those tiny watches) immediately under the dial, set in motion once every hour, and bringing the corresponding numbers under the aperture E. CHATEL

Jersey, January 5

THE COAL QUESTION

IT is generally admitted that the amount of coal existing below Great Britain at such depths that it can be worked is limited, that large quantities of coal are annually used, and that even the partial exhaustion of the fields, accompanied, as it must be, by a rise in price, would seriously affect almost all our manufactures, and greatly endanger our commercial supremacy. But if we attempt to go further, and say how long our supply of coal will last, we meet with very different estimates. Nearly a hundred years ago the question was discussed by Mr. John Williams, and though the insufficiency of the data did not allow him to give a definite answer, he at least showed the vital importance of the subject.

In 1861, Mr. Hull, by taking into account the area of all our coal-fields and the thickness of the workable seams, calculated that the total available coal in Great Britain was 79,843,000,000 tons; this result was shown by a second calculation to be slightly too low. Further, he assumed that the output of coal, which was then 86,000,000 tons, could not rise much above 100,000,000, and therefore that our supply was sufficient for eight centuries.

Four years later Prof. Stanley Jevons, in an admirable essay on "The Coal Question," accepted the more important of Mr. Hull's data, but showed that they would bear a very different interpretation, and that, instead of the eight centuries spoken of by Mr. Hull, "rather more than a century of our present progress would exhaust our mines to the depth of 4000 feet." He then shows that the absolute physical exhaustion of the fields is improbable, but that before the twentieth century is far advanced the output of coal will probably be checked by a rise in price so considerable that England will be unable to compete in manufactures with other nations still enjoying the profusion of coal to which her present commercial prosperity is so greatly due. These theories and results were reviewed and strengthened by Prof. Marshall in 1878 ("Coal, its History and Uses"), with the aid of more recent statistics; and the present paper is intended to give a short and simple account of the present state of the question from the physical side, with the omission of the more difficult and dubious arguments which may be drawn from Political Economy.

The arguments of Prof. Stanley Jevons were so conclusive, and his results so alarming, that a Royal Commission, of which the Duke of Argyll was chairman, was appointed, in 1866, to investigate the probable quantity of coal contained in the coal-fields of Great Britain. In 1871 the Commission reported that the coal-fields already in use still contained 90,207,000,000 tons of coal, and that concealed coal-fields as yet unopened, near Doncaster, Birmingham, and elsewhere, probably contained 56,273,000,000 tons more, or that, in all, 146,480,000,000 tons of coal were available. Since that time about 1,780,000,000 tons of coal have been raised, leaving as the available supply in 1884 about 144,700,000,000 tons. Subsequent investigations show that this estimate is probably considerably too high.

These results were intended to include all beds a foot and upwards in thickness lying within 4000 feet of the surface, though it was rendered probable at the same time that the amount of coal below 4000 feet is not very large. The reason for excluding all beds less than a foot thick is that, at present prices, it is found unprofitable to work them, and hence, except in a few special cases, they are left untouched, though rendered worthless for the future from the disturbance of the strata occasioned by working the other beds.

Though we may assign no limit below which it is impossible to work, the cost of mining increases so rapidly with increased depth that the price of coal must rise very seriously before even the 4000-foot limit can be reached. This increase of cost depends upon various causes. The mere sinking of three shafts like those of Murton, which are said to have cost 300,000*l.*, burdens the undertaking, if it last fifty years, with an interest and sinking fund at 4 per cent. amounting to 13,965*l.* per annum. More powerful winding and pumping engines must be employed, and from the great expense of shaft-sinking, larger areas must be worked from one shaft, necessitating extra expense in underground haulage, ventilation, and supports. Further, each actual coal-hewer requires a larger amount of assistance to secure his safety and to remove his winnings in a deep pit. A coal-hewer working at an open seam on the surface of the ground would only require one labourer to wheel away the coal, while in a deep mine each hewer requires about three men to attend to the removal of the coal, the pumping, and ventilation.

The high temperature of the rock at great depths is also an important factor in the expense of deep mining. In England there is found to be a uniform temperature of 50° F. about 50 feet below the surface; but this temperature is found to increase 1° F. for every 60 feet descended, so that at 4000 feet the temperature of the rock will be about 116° F. And though this temperature is not sufficiently high to prevent working, and might be lowered a few degrees by ventilation, it will cause a considerable increase in the expense, both from the lassitude and extra pay of the men, and the larger amount of air required, which even now at Hetton amounts to 450,000 cubic feet per minute.

These difficulties account for the manifest reluctance to sink deep pits, for the high price charged for the coal from them, and for the fact that the 4000-foot limit has not yet been approached. In 1846 the Messrs. Pemberton's pit at Monkwearmouth reached 1720 feet; in 1858 the Astley pit at Dukinfield reached 2100 feet; in 1869 the Rosebridge pit at Wigan reached 2448 feet; in 1881 the Ashton Moss pit near Manchester reached 2688 feet; and though the Lambert pit in Belgium has been worked at 3490 feet, the circumstances were exceptional, and it is certain that the commercial success of such a pit in England would necessitate a price of coal far higher than it at present is.

The early estimates of the annual output of coal are so unreliable that it is useless to go back further than 1854, when "Mineral Statistics" were first carefully collected by Mr. Robert Hunt, and even in these returns the amounts for the first few years are possibly as much as three per cent. too low, from the difficulties of overcoming the fears of the coal-owners as to the uses which might be made of them. These returns have been collected and arranged by Mr. Meade, in his "Coal and Iron Industries

of the United Kingdom," from which Columns I. and V. of the following table have been for the most part taken.

Since the amounts of coal used are very large, and great accuracy cannot be expected in inquiries of this nature, it is convenient to take as the unit of our calculations 1,000,000 tons of coal instead of our ordinary unit, the ton. This unit may be expressed in several different ways: a cubic yard of anthracite weighs about 2700 lbs., and of bituminous coal from 2090 to 2400 lbs., hence on an average a cubic yard of coal weighs a ton; and our unit of 1,000,000 tons is a cubical block of coal 100 yards each way, or a bed of coal a mile square and a foot thick. Column I. in the following table gives the annual output of coal since 1854, and the total output during the thirty years, which amounts to 3,245,100,000 tons.

Amount of Coal in Million Tons

Year	I. Won	II. Calculated $64\cdot7+3(n-1)$	III. Calculated $62\cdot85 \times 1\cdot035^{n-1}$	IV. Calculated $65\cdot5 \times 1\cdot0325^{n-1}$	V. Exported
1854	64·7	64·7	62·9	65·5	3·4
1855	64·5	67·7	65·0	67·6	5·1
1856	66·6	70·7	67·3	69·8	5·9

1861	86·0	85·7	80·0	81·9	7·9
1862	81·6	88·7	82·8	84·6	8·4
1863	86·3	91·7	85·7	87·4	8·3
1864	92·8	94·7	88·7	90·2	8·9
1865	98·2	97·7	91·8	93·1	9·3
1866	101·6	100·7	95·0	96·1	10·1
1867	104·5	103·7	98·3	99·3	10·6
1868	103·1	106·7	101·7	102·5	11·0
1869	107·4	109·7	105·3	105·8	10·7
1870	110·4	112·7	109·0	109·3	11·7
1871	117·4	115·7	112·8	112·8	12·7
1872	123·5	118·7	116·8	116·5	13·2
1873	127·0	121·7	120·8	120·3	12·6
1874	125·1	124·7	125·1	124·2	13·9
1875	131·9	127·7	129·4	128·2	14·5
1876	133·3	130·7	134·0	132·4	16·3
1877	134·6	133·7	138·6	136·7	15·4
1878	132·6	136·7	143·5	141·1	15·5
1879	134·0	139·7	148·5	145·7	16·4
1880	147·0	142·7	153·7	150·4	18·7
1881	154·2	145·7	159·1	155·3	19·6
1882	156·6	148·7	164·7	160·4	20·9
1883	163·8	151·7	170·4	165·6	22·8
Totals	3245·1	3246	3245·1	3251	351·7

A few comparisons may enable the mind to grasp the real meaning of these enormous figures. It was calculated by Sir Henry Bessemer that the output of coal, 154,000,000 of tons for the single year 1881, would suffice to build 55 Great Pyramids, or to rebuild the Great Wall of China, and to add a quarter to its length! In 1883 the output was 163,800,000 tons, which would form a column a mile square and nearly 164 feet high; or would build a wall from London to Edinburgh 400 miles long, and 45 feet 9 inches high and thick, or another round the world 24,000 miles long, and 5 feet 11 inches high and thick; or, if the Straits of Dover are 21 miles across and 600 feet deep, would make an embankment across them 22 yards wide: while the total output for the 30 years would build a round column 9 feet 4 inches in diameter, which would reach 240,000 miles high, the distance of the moon.

The numbers show considerable fluctuations—as might be expected from the variety of accidental circumstances, such as new inventions, the mean annual temperature, and the state of trade, which affect the amount of coal used—but, on the whole, a very rapid increase; the output for 1875 being double of that for 1854, and that for 1883 double of that for 1862.

If we assume that the increase in annual output would be constant were it not for accidental circumstances, we can represent the actual numbers, with fair accuracy, by an arithmetical series of which the first term is 64·7, and the last 151·7, the increase in annual output being 3, and the total amount 3246 (Column II.). Further it has been shown that the coal still available in 1884 is 144,700,000,000 tons, and we may assume that the output in 1884 will be at least as great as that in 1883, or 163,800,000 tons. Hence, if the output of coal continues to increase at the rate of 3,000,000 tons annually, our supply will last for 261 years, or will be exhausted about A.D. 2145.

But this calculation is open to several objections, and the numbers as shown by Prof. Stanley Jevons may bear a much more serious significance.

It is improbable that the annual difference should always remain the same, and in fact, in the calculated series (Column II.), while all the early terms are higher than the real outputs, the later terms are lower, showing that the difference itself probably increases. If we calculate the series backwards we have no output at all about 21 years before 1854, a result we cannot agree with, and for all years before 1833 a negative output, a result we cannot understand. Hence it is probable that the results may be better expressed by another kind of series.

Theory and experience show that the same causes always produce the same effects, unless fresh circumstances intervene to modify the effects produced. Thus the population of England, which was about 9,000,000 in 1801, became 18,000,000 in 1851, or doubled in 50 years; hence, if no new causes intervene, we should expect it to double again in the next 50 years, or to become 36,000,000 in 1901. This is usually expressed by saying that social statistics in general show uniform multiplication in uniform periods, or obey the compound-interest law, or form a geometrical series. As an example of this law let us examine a little more closely the population of England and Wales. The increase for each 10 years since 1801 is itself perpetually increasing, or the numbers must be expressed by a geometrical series of which the ratio is nearly 1·147, and not by an arithmetical series.

Year	1,000,000 Inhabitants	Increase in Ten Years	Calculated $8\cdot89 \times 1\cdot147^{(n-1)}$
1801	8·89		8·89
1811	10·16	1·27	10·20
1821	12·00	1·84	11·70
1831	13·90	1·90	13·42
1841	15·91	2·01	15·39
1851	17·93	2·02	17·65
1861	20·07	2·14	20·24
1871	22·71	2·64	23·22
1881	25·97	3·26	26·63
Sum	147·54		147·34

From the dependence of the numbers representing the annual output of coal upon the number of inhabitants, it might be expected that they also can be expressed by a geometrical series, and this has been shown by Prof. Stanley Jevons to be the case. According to his calculations the ratio of the series is about 1·035, or the rate of increase of the output is about $3\frac{1}{2}$ per cent per annum, and it may be assumed for the reason before given that the sum of all the outputs is likely to be more approximately correct than the single output for 1854. The annual outputs calculated from these data are given in Column III., and show a fair approximation to the actual numbers, though the first term is rather low, and the last six terms are nearly as much above the true results as those in the

arithmetical series were below them. In fact, either from a prolonged fluctuation in trade, or from the operation of the cause we are discussing, the outputs for the last six years have not increased so rapidly as the previous numbers would lead us to expect. The outputs for the years 1854-77 are very fairly expressed by a series of which the first term is 63·9 and the ratio 1·0355, but this series makes the last six terms far too high.

Again the ratio 1·03 gives 71 as the first term, and makes all the early terms considerably too high. In short, the fluctuating numbers in Column I. seem to be best expressed by a series of which the first term is 65·5 and the ratio 1·0325; the outputs calculated from these data are given in Column IV.

It is easy also to calculate backwards and obtain earlier terms in the same series, thus for 1840 an output of 43,000,000 tons is given, and for 1800 one of 11,700,000, instead of Mr. Hull's conjecture of 36,000,000 and 10,000,000 tons respectively. And taking the true output of 163,800,000 of tons in 1883 and the ratio 1·0325, we can calculate the probable output for any future year. Thus for 1901 we obtain 282,000,000 tons instead of 331,000,000 as calculated by Prof. Stanley Jevons. Further, a well-known formula gives the sum of any number of terms of the series, or we can calculate in how many years the amount of coal raised will be equal to any given amount, say to the 144,700,000,000 tons remaining in 1884. Making the calculation, we find that if the present rate of increase in the consumption of coal of $3\frac{1}{4}$ per cent. per annum continues, or, in other words, if our output of coal continues to double every 22 years, our total supply will be exhausted in 106 years from 1884, or about A.D. 1990.

Of course no one can suppose that our consumption will continue to increase until it comes to a sudden and final end, but only that within a comparatively short period our output of coal must reach a maximum, and then gradually diminish as it becomes more scarce and expensive.

These calculations, then, seem to force upon us one of four possible conclusions:—Some new source of energy may be found to supply the place of coal; a larger proportion of the energy contained in our coal may be utilised, so that an output as large as the present one may produce a much larger amount of useful work; coal may be imported from other countries to supply our deficiencies; or lastly, the commerce and manufactures of England may pass into a stationary or retrograde condition.

Coal is used directly as a source of heat in our domestic fireplaces, as a source of mechanical energy indirectly in our steam- gas- air- and electric-engines, and as a heating and reducing agent in our metallurgical furnaces. A pound of fairly good coal will heat about 13,000 lbs. of water through 1° F., and in an ordinary steam boiler about 8000 of these units of heat are utilised, which suffice to turn rather more than 7·3 lbs. of water at ordinary temperatures into steam. But the unit of heat is able to do work to the extent of raising 775·4 lbs. through one foot in opposition to gravity. Hence, by burning one pound of coal, rather over 10,000,000 foot-pounds of work may theoretically be obtained. A first-rate steam-engine does effective work to the extent of about one-ninth of the theoretical amount. Hence, in round numbers, a pound of coal will do 1,000,000 foot-pounds of work, or as much work as is done by 32 ordinary men in ascending the 202 feet to the top of the Monument. According to Péclet, a pound of average coal contains ·804 lb. carbon, ·0519 lb. hydrogen, and ·0787 lb. oxygen, and would therefore theoretically suffice to reduce $8\frac{1}{4}$ lbs. of hematite with formation of $5\frac{3}{4}$ lbs. of iron. Any complete substitute for coal must be able to perform each of these three duties of coal.

It seems improbable that any new source of energy on the large scale will be discovered, though possibly small engines may be driven by some form of explosive, and hence tides, winds, and waterfalls alone, have to be considered as substitutes for coal. According to Sir William Thomson, energy in the form of electricity might be conveyed for 300 miles through a copper rod with a loss of only 20 per cent. from such a waterfall as Niagara, and stored up in secondary batteries for distribution. It is only necessary, without going into details of expense, to point out that we have no monopoly of winds, tides, or torrents, such as we have had of coal, and in fact, were they the sources of energy, we should compete with our neighbours rather at a disadvantage.

The next point to consider is how far more economical methods of obtaining and using our coal may reduce the output. It has been already pointed out that, as with coal at its present price it is not commercially possible to work seams less than a foot thick, all such coal is wasted. Large quantities of coal also are more or less unavoidably wasted in the processes of cutting and carrying, and it seems as if any great reduction in this amount must be accompanied by a considerable rise in price.

The uses to which our coal is applied, may, for the purposes of this inquiry, be roughly grouped under four heads—mining and metallurgy; manufactures, and locomotion on land and sea; domestic uses, including the supplies of gas and water; and lastly, for export. Under the first three heads, no doubt, large saving is possible, but it is not likely to be begun except under the pressure of a scarcity of coal, when the high price of the coal will cause the introduction of more expensive and more efficient machinery.

By far the most important metallurgical operation is the production of iron, which may therefore be taken as an example of the others. In 1788, 7 tons of coal were used per ton of pig-iron produced, which sank to 5 tons about 1800. The introduction of the hot blast in 1829 caused a further drop to $3\frac{1}{2}$ tons in 1840; and that of regenerators in 1857 caused a further fall to $2\frac{1}{2}$ tons in 1875. But the increase in the quantity of iron manufactured renders the actual saving of coal very small. In 1881, 18,300,000 tons of coal were used in making 8,300,000 tons of pig-iron, and a nearly equal amount of coal was required to convert five-eighths of the pig into wrought iron and steel. So that, in all, the iron-works required 34,700,000 tons of coal.

Experience seems to show that, though our best steam-engines give an efficiency of one-ninth, and the efficiency of air- and gas-engines is even higher, except in special circumstances, it is commercially preferable to use less efficient engines; the saving of coal at present prices being more than compensated for by the higher cost of the better engine. It is possible, however, that in the future electric engines may be used of far greater efficiency than our present steam-engines. On the other hand, the high rates of speed now demanded both for passengers and goods necessitates the consumption of large quantities of coal. Thus on a level railway a ton of load requires a pull of about $16\frac{1}{2}$ lbs. to draw it at the rate of 29 miles per hour, while, if the rate be increased to 50 miles per hour, the pull is nearly 33 lbs. Hence the 13,500 locomotives in Great Britain will require much more coal to drag the same loads at the higher rate. Our merchant navy also is being rapidly converted from sailing into steam vessels; in the 14 years 1866-1879, the number of sailing vessels *decreased* 5600, while the steamers *increased* 2200; and the steamers engaged in the foreign trade used in 1881 5,200,000 tons of coals, in 1882 5,600,000, and in 1883 6,400,000.

The aggregation of people in towns requires the use of coal for the production of gas or electric lighting, frequently for the removal of sewage and refuse, and for the supply of water. Possibly the most wasteful use to which coal is applied is our common domestic fireplace. But it would require an enormous increase in the price of coal to induce the average Englishman to convert his genial,

wasteful, open fireplace into the dull, though economical Continental stove.

The trade in coal and coke, especially to France, Germany, Russia, and Sweden, has reached very considerable dimensions, and is, in fact, the fourth most important of our exports. In Column V. it will be noticed that the 3,400,000 tons exported in 1854 have become in 1883 22,800,000 tons, worth more than 8,000,000*l*., or in thirty years the export of coal has multiplied more than six times. Any considerable lessening in this amount would of course seriously affect the balance of our trade with other countries.

It seems hardly necessary to meet the objection that when our own stores are exhausted we may import coal from other countries. A few considerations will show the fallacy of such reasoning. The nearest stock of coal on which we can hope to draw is that in Canada and the United States. The former supply is plentiful, but much of it is badly situated for exportation. In the United States coal is found in Virginia, Utah, and the Western States, and the basin of the Mississippi and its tributaries contains coal-fields estimated to cover 200,000 square miles, and to contain about 38 times as much available coal as Great Britain. According to Mr. Hull, these fields could as easily supply an output of 2,704,000,000 tons as we can one of 90,000,000.

Putting aside the commercial difficulties dwelt on by Prof. Stanley Jevons in the way of converting a large export trade in our staple raw material into an immensely larger import trade, the fact that even now the rivalry with the ingenuity and perseverance of the American manufacturers, aided though we are by their high tariff, demands all our skill and energy, and the almost universal law that manufactures cluster round the source of power, the physical difficulties of such a traffic would be enormous. Suppose a steamer similar to the *Faraday* capable of carrying 6000 tons, and so swift as to be capable of making 13 trips from America in the year; she would annually bring 78,000 tons of coal, or it would require a fleet of 2100 such ships to supply even our present requirements. And if the coal could be supplied to our shipping in American ports at 10*s*. a ton, we should have annually to pay America 81,900,000*l*., an amount not far below our present national income. The further cost of carriage across the Atlantic and delivery in English towns, must raise the price of coal to many times what we at present pay.

We are brought, then, face to face with the last of the four above-mentioned possibilities. Before very many years are past we must expect that the scarcity of coal in England will cause a considerable rise in price, which will directly affect all such branches of trade and manufactures as depend upon coal, and indirectly all other branches.

What this means in the former case will be evident from a brief consideration of the uses to which coal is applied, a few instances of which have already been given. Let us take one instance of the latter class—the importation of food-stuffs. The increase in the population of England per square mile, which was 37 in 1066, 75 in 1528, 140 in 1780, 241 in 1831, and 443 in 1881, higher than any civilised country except Belgium, has taken place far more in manufacturing than in agricultural districts, and has necessitated a great change in our supply of food. Previous to 1780, though luxuries were imported, the staple food-stuffs, corn, meat, cheese, &c., were produced at home; now, on the other hand, we import more than one-third of our meat, half of our cheese, and nearly two-thirds of our wheat. Owing to our luxuriousness and to this large importation of food, averaging 212 lbs. annually per head, the average annual cost of food per head in England, 13*l*. 9*s*., is higher than that in any other country. When by the scarcity of our coal our pre-eminence in heapness of manufactures becomes a thing of the past, the means of paying for this food will gradually cease, and the pressure of population, together with the increased cost of the necessaries of life, by emigration, by an increased death-rate, and by a reduced birth-rate, will change the England of to-day into a country like the England of 1780,—a country with a comparatively scanty population, with few manufactures, supporting themselves by the produce of their fields, and looking back on the England of to-day as the Spaniard now looks back on the Spain of Philip II.—of Philip, the husband of Mary of England, the ruler of Spain, Portugal, the Netherlands, the Milanese, of Malabar, Coromandel, and Malacca—of Philip, whose father had sent Cortez to conquer Mexico, and Pizarro to Peru, and who himself, by the conquest of Portugal, had annexed the valuable province of Brazil. Looking at such a picture, is it impossible that the England which now rules over 8,600,000 square miles, containing 283,000,000 inhabitants, should shrink to its former limits of 122,000 square miles, with 8,000,000 inhabitants?

Finally, let us consider if anything can be done to defer or mitigate this change in the condition of our descendants. After discussing and rejecting the expediency of limiting or taxing our output or export of coal, on the ground that any such measure would impose a serious burden upon our manufactures and commerce, and in fact produce the very result we are trying to avoid, Prof. Stanley Jevons proposed that instead of relieving ourselves by the remission of taxation, we should relieve our descendants by making a serious effort to pay off the National Debt. The amount of the debt, which was 900,000,000*l*. in 1815, was 839,918,443*l*. in 1857, and 756,376,519*l*. in 1883. Thus in 68 years about 144,000,000*l*. have been paid off. He proposed that the probate, legacy, and succession duties, as being in reality capital and not income, should be applied to this purpose. These duties amounted in 1883 to about 5,600,000*l*., and would suffice to pay off the National Debt in about 55 years. These proposals have been in part carried out. The amount of taxes remitted has of late years been considerably reduced, and in 1883 terminable annuities were created, which in 20 years will reduce the debt by 173,000,000*l*.

On the other hand, the rapid increase in local obligations to some extent renders nugatory this attempt at national economy. It is somewhat difficult to obtain accurate data on these points, but the bonds of the Metropolitan Board of Works, of Liverpool, of Manchester, and of Leeds, quoted on the Stock Exchange, represent a sum of 34,000,000*l*., and no doubt other towns are following far too rapidly in the same direction. Of course some of this expenditure represents profitable enterprises, such as the supply of gas and water, but it is to be feared that a considerable amount has been spent in ways less directly or indirectly remunerative.

If, then, we are unable to arrest the action of those physical and commercial laws which will press with more and more severity on our descendants, let us do what we can to mitigate their fate by using every exertion to avoid unnecessary increase in our obligations, and to reduce those transmitted by our fathers. It would probably be well also to appoint a fresh Royal Commission to investigate more accurately than has yet been done the various data upon which these calculations depend, to make more widely known any improvements made during the last thirteen years which may prolong the duration of our coal, and to consider the most important financial questions which are involved in this inquiry.

And at last, when the worst comes to the worst, we may take comfort from the thought that, beyond the four seas, new Englands, as yet hardly conscious of their capacities, stretch east and west, and that the New Zealander, who a few years hence may moralise on the last stone of London Bridge, will mingle reverence with his philosophy, for he will be no dark-skinned, far-off cousin, but a ruddy, healthy grandchild.

SYDNEY LUPTON

INVIGORATION OF POTATOES BY CROSS-BREEDING

SOME interesting experiments on the potato were tried at Reading last summer. Most persons are aware that changes which are called "improvements" from a commercial point of view have been effected among the plants of the farm and garden in recent years by "hybridising," and that the usual result of hybridising plants is to invigorate them. Mr. Darwin explains the law which horticulturists avail themselves of in the improvement of plants when he says, "All forces throughout Nature tend towards an equilibrium, and for the life of each organism it is necessary that this tendency should be checked" ("Animals and Plants under Domestication," vol. ii. p. 130). He adds, hence "the good effects of crossing the bre d, for the germ will be thus slightly modified or acted on by new forces." The invigoration consequent on changing seed corn from one district to another is due to the same causes, as well as the "evil effects of close interbreeding prolonged during many generations, during which the germ will be acted on by a male having almost identically the same constitution."

It would not be easy to ascertain the history of cross-breeding in gardens. Hybridisation has been called "a game of chance played between man and plants." All the great breeders of florists' flowers, and of fruits and vegetables, have practised the art successfully, but as regards the potato recent investigations have shown that the law of "changed conditions" has not been obeyed. The term "hybridising," as used by horticulturists, is a relative expression, referring sometimes to the crossing of widely distinct forms, and in other cases to the injurious union of closely connected forms. Hitherto the breeding of potatoes has involved this vicious principle of too close interbreeding, no other plant of the farm having been more constantly intercrossed.

Some years since the cross-breeding of English and American potatoes was extensively practised, and to some extent, undoubtedly, the "conditions of life" of the varieties which were brought together from either side of the Atlantic were changed; but the cultivated potatoes both of England and America belong to the same species, and having both alike become enfeebled and subject to the same disease, the experiment of interbreeding failed in its object.

Under these circumstances a veteran breeder wrote, "I have come to the end of my tether!" and he gave up the breeding of potatoes in despair. This year he has recommenced it, working hopefully with the aid of a new species, and owing this new departure to the suggestion of the eminent botanist Mr. J. G. Baker, F.R.S., of Kew.

Mr. Baker undertook a scientific examination of the various tuber-bearing species of Solanum, for the purpose of ascertaining whether *S. tuberosum*, the cultivated potato, might not possibly be invigorated by hybridising it with some other species of the family. Writing in the *Journal* of the Linnean Society, Mr. Baker says:—

"The subjects of the differential characters, the relationship to one another, and the climatic and geographical individuality of the numerous types of tuber-bearing Solanums are of great interest both from a botanical and economic point of view. As there are many points which are still to be unravelled, I propose in the present paper to pass in review the material which we possess in England bearing on the question. It was at the instigation of Earl Cathcart that I undertook the inquiry; and in carrying it out I have gone through all the dried specimens at Kew, the British Museum, and the Lindley Herbarium, have carefully studied the wild types which we grow in the herbaceous ground at Kew, and have visited the extensive trial-grounds of Messrs. Sutton and Sons at Reading, whose collection of cultivated types in a living state is probably the most complete in existence."

Bearing in mind that the potato, the most productive of our food-plants, has become the most uncertain among them in regard to its annual produce, it is not surprising that it should have been the subject of voluminous writing and continual inquiry. But, in spite of all the pains which have been expended on this stricken esculent, no one but Mr. Baker seems to have recognised the outrage of in-and-in breeding to which it has been subjected. It seems doubtful whether the numerous breeders were aware that the cultivated potato had been made the subject of continual in-and-in breeding, since it had never been crossed out of its own family during the 250 years of its highly artificial treatment in this country as a cultivated plant. Yet this has been the case, as Mr. Baker shows in his enumeration of the six tuber-bearing species of the plant. As the habitat as well as the distinctions of species of Solanum affect the subject, the following brief details have been taken from Mr. Baker's paper:—

"(1) *S. tuberosum.*—Andes of Chili, Peru, Bolivia, Ecuador, and Columbia; also in the mountains of Costa Rica, Mexico, and the South-Western United States.

"(2) *S. Maglia.*—Shore of Chili, down south as far as the Chonos Archipelago; also likely Peru.

"(3) *S. Commersoni.*—Uruguay, Buenos Ayres, and Argentine Territory, in rocky and arid situations at a low level.

"(4) *S. cardiophyllum.*—Mountains of Central Mexico, at an elevation of 8000 to 9000 feet.

"(5) *S. Jamesii.*—Mountains of South-Western United States and Mexico.

"(6) *S. oxycarpum.*—Mountains of Central Mexico."

According to Bentham and Hooker, the great genus of Solanum—the largest in the world—consists of decidedly distinct species, and if we omit some of the so-called species which are really only varieties of *S. tuberosum*, these six species alone bear tubers.

In attempting improvement by crossing the cultivated potato, it is useless to continue the system of interbreeding with its own varieties; and, on the other hand, the lesser forms of wild potatoes, such as *S. Jamesii*, a plant of eight or ten inches in height, must be rejected. Mr. Baker recommends two species as best for the breeders' purpose, *S. Maglia* and *S. Commersoni*. Both these kinds yield good crops of fair quality under cultivation, and they possess the advantage of coming from a moist climate. This is a point of great importance. When Mr. Darwin, a young naturalist in 1835, was writing his account of "The Voyage of the *Beagle*," he mentioned having seen the potato growing wild on the shores of the islands of the Chonos Archipelago, in South America, and he thought it surprising that the same plant should be found in the damp forests of those islands and on the sterile mountains of Central Chili, where a drop of rain does not fall for more than six months. The explanation of this anomalous circumstance is that the potato of the islands and lowlands belongs to a different species from that of the mountains, the latter being identical with the cultivated potato of Europe and America, while the former is *S. Maglia*, which is at any rate hardy, vigorous, and healthy, and in all respects apparently well suited for crossing with the cultivated sorts. This is the potato which Mr. Baker recommends. Earl Cathcart had asked him for any suggestions that a botanist might be able to offer to breeders founded upon scientific knowledge of the potato generally and of the geographical distribution of the family.

On this part of his inquiry, Mr. Baker observes that potato-growers work upon the assumption that the one purpose of the plant's existence is the production of potatoes, which is in fact only an incident in its life. *S. Maglia* has been grown at Kew among the herbaceous plants since 1862, and in that dry sandy soil, without manure, it produces few if any tubers, or only of small size. On the other hand, two tubers were sent to Chiswick and grown there in the gardens of the Royal Horti-

cultural Society in richly-manured land, and the produce proved abundant, yielding, the first year, 600 tubers as large as pigeons' eggs. The constitutional effects of the abnormal production of tubers which high farming occasions have been often noticed. On this point Mr. Baker says: "Any plant brought to the tuber-bearing state is in a disorganised, unhealthy condition, a fitting subject for the attacks of fungus and aphides."

It frequently happens, moreover, that the cultivated potato loses its power of producing flower and of reproducing itself by means of seed. The illustrious horticulturist, Thomas Andrew Knight, discovered the relationship of tuber to fruit, and demonstrated with great clearness the principle that, in proportion as plants or animals waste in one direction, they must economise in another. Knowing the difficulties that lay in the path, Lord Cathcart intrusted some tubers of *S. Maglia* from the coast of Chili to those eminent potato-breeders, whose collection of varieties Mr. Baker refers to as the largest in the world, Messrs. Sutton and Sons of Reading. After very careful treatment of the tubers, which were about the size of walnuts, the young plants were committed to the open ground, where, making our story as short as possible, they grew vigorously and produced numerous blossoms having white corollas, which are characteristic of wild potatoes, the corollas of cultivated breeds being purple and lilac. But whatever the seed-bearing capabilities of *S. Maglia* may be at Valparaiso and in the Chonos Archipelago, when growing in a state of nature, it did not produce a single seed in Messrs. Suttons' trial-grounds, except in the case of some blossoms which were hybridised. It is needless to describe the particular means by which this delicate operation was effected. It happens, however, that the manipulator was the same veteran breeder who had grown despondent about potatoes until this new departure had been achieved. Last winter he had reached the end of his tether. Since then he has hybridised *Solanum Maglia*, and is anticipating the conquest of new potato worlds in his old age.

The crop at Reading this first year is good, and the tubers are as large as those of ordinary potatoes. The foliage is luxuriant, growing as high as a common table. Certain other sorts have shown no capacity for "improvement." *S. Jamesii*, for example, grows at Reading only eight or ten inches high, and would scarcely be recognised as a potato except by a botanist. *S. Commersoni*, known by the synonym *Ohrondi*, from the name of a French naval surgeon who brought it to Brest from Goritti Island, at the mouth of the Rio de la Plata, was obtained last spring by Messrs. Sutton from M. Blanchard of the Gardens of the Naval Hospital at Brest. Messrs Sutton have wisely acted throughout these trials under scientific advice, and *S. Commersoni* had been named by Mr. Baker as one of the few species which are known at present to have shown a capability of "improvement." Unfortunately it resisted all the attempts that were made last summer at Reading to hybridise it with the cultivated sorts. We may hope, however, to become possessed of this and other hybrids before breeders have travelled far on the road which has now been opened to them. Previous attempts to overcome the potato disease had been mainly directed to the doctoring of the soil, or plant, and to direct attacks upon the disease. Every gardener and farmer may now welcome the birth, so to speak, of a hybrid, which, we may hope, will enable the potato plant to resist the attack of parasites, and especially those of the devastating fungus *Peronospora infestans*. H. E.

ON THE EVOLUTION OF THE BLOOD-VESSELS OF THE TEST IN THE TUNICATA

It is well known that the test or outer tunic in most Simple Ascidians is penetrated by a system of tubes containing blood. These "vessels" were shown in 1872 by Oskar Hertwig[1] to be developed as ectodermal evaginations containing prolongations from one of the blood-sinuses of the underlying mantle. Each vessel is divided longitudinally into two distinct tubes by a septum of connective tissue, and after ramifying through the test may be found to terminate, generally close to the outer surface, in one or more rounded enlargements or bulbs which are usually known as the "terminal knobs" (Fig. 5, B). The two blood-tubes join in the terminal knob where the septum ends, and this allows the blood which flows outwards through the one tube to turn in the bulb and flow back

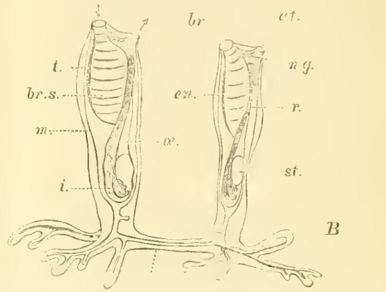

Fig. 1.—*Clavelina lepadiformis.* Enlarged from a specimen dredged off Dartmouth. *br*, branchial aperture; *at.*, atrial aperture; *br.s*, branchial sac; *t*. test; *m*, mantle; *œ*, œsophagus; *st.*, stomach; *i*, intestine; *r.*, rectum; *en.*, endostyle; *n.g*, nerve ganglion; *s.*, stolon; B, part of the stolon becoming enlarged to form a bud.

along the other tube. Thus temporarily the one tube acts as an artery and the other as a vein, but of course they exchange functions at each reversal of the heart's action.

This system is usually regarded as being merely the blood-supply to the test; but Lacaze-Duthiers[2] has pointed out that the hair-like projections from the test to which sand-grains adhere in most Molgulidæ, are merely special developments of the terminations of the vessels, and I have suggested[3] that they are also homologous with the vessels in the stolon of the Clavelinidæ from which buds are produced (Fig. 1).

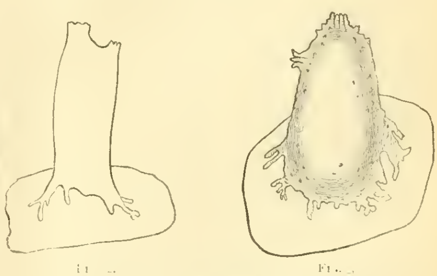

Fig. 2.—*Ciona intestinalis* from Lamlash Bay, Arran. Natural size.
Fig. 3.—*Ascidia aspersa* from Lamlash Bay, Arran. Natural size.

The extent to which this blood-system of the test is developed varies greatly in the different species of Simple Ascidians. In some, such as *Ascidia plebeia* and *Corella parallelogramma* (Fig. 4), it is very rudimentary, if indeed it can be said to be present; while in others, such as *Ascidia mentula*, *Ascidia meridionalis*, and *Ascidia*

[1] "Untersuchungen über den Bau und die Entwickelung des Cellulose-Mantels der Tunicaten," *Jenaische Zeitschrift*, Bd. vii. p. 46.

reptans, the test is penetrated in all directions by a well-developed system of tubes with large and numerous terminal bulbs. A series of Simple Ascidians could be formed showing all conditions between these two extremes, and also exhibiting very varied arrangements in regard to the disposal of the vessels in the test, their modes of branching, and the relative numbers and sizes of the terminal bulbs. But perhaps the most interesting modifications of all are those met with in some of the members of the remarkable deep-sea genus *Culeolus*. There we find a great development of the vessels and their enlargements just on the surface of the test, and separated from the surrounding medium by a very thin layer of tissue. When describing this system in 1882,[1] I suggested that in these species it might act as an accessory organ of respiration, and I have lately shown[2] that an investigation into the condition of the corresponding system of vessels in some of the Compound Ascidians supports this idea, the chief arguments in favour of which are:—

(1) The disposition of the tubes and cavities in the different regions and layers of the test, and the anatomical characters of the system.

(2) The relation which exists in many groups of Ascidians between the branchial sac (the chief organ of respiration) and the system under discussion,—where the branchial sac is large and highly developed, the vessels in the test are few and small; but where the branchial sac is small, simple, and apparently inefficient, the vessels in the test are numerous, of large size, and disposed in such a manner as to suggest that they are concerned in the aëration of the blood.

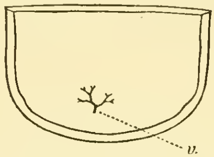

Fig. 4.—*Corella parallelogramma*. The posterior part of the left side of the test of a specimen from Loch Fyne. Twice the natural size. *v.*, the system of vessels.

It is obvious that it would be advantageous to an Ascidian if its test could act even to a slight degree as an accessory respiratory organ, by allowing the blood circulating in its superficial layers to be brought into such close relation with the external medium as to render possible a certain amount of oxidation. And consequently it is easy to imagine the process of evolution of such a complicated system as we find in *Culeolus murrayi* from a few simple vessels like those in the test of *Corella parallelogramma* (Fig. 4). But it is probable that the common ancestor of Simple and Compound Ascidians had no blood-spaces in its test. There are none in the "Haus" of the Appendiculariidæ; and in *Clavelina*, which may be regarded as nearer to the first Simple Ascidian than any other form known, there are no vessels in the test except those of the stolon. Some structure must therefore be looked for from which the first respiratory blood-system of the test may have been evolved, and such a structure is to be found, I believe, in the gemmiparous stolon of the Clavelinidæ.

Clavelina (Fig. 1), which from other independent evidence I regard as the most primitive form of Simple Ascidian known to science, is one of the so-called "Social" Ascidians in which the members of the colony are united by a creeping stolon containing "vessels" (that is a prolongation of the ectoderm and the mantle, and a blood-tube) which place the circulatory systems of the various members in communication, and from the ends of which, in prolongations of the test (as at B, Fig. 1), new members are produced by gemmation. It is possible that this system may act in some slight degree as a respiratory organ, but its chief function, and probably its only one, is the asexual production of new individuals.

The ancestors of the remaining Simple Ascidians diverged from the ancestors of the Clavelinidæ, and lost the power of reproducing by gemmation, but in many of the least modified of the Ascidiidæ we still find processes from the posterior end of the test which contain vessels, and so closely resemble the stolon of *Clavelina* in all particulars that there can be no doubt that they are persistent rudiments of that structure.

In *Ciona*, which is certainly one of the most primitive of the Ascidiidæ, vessels are only present in the posterior part of the test, and here we frequently find them drawn out into long processes of the test, which have the greatest possible resemblance to stolons (Fig. 2), and are doubtless their homologues, although they no longer function as bud-producing organs. They are useful as adhering organs, and they have probably to a slight extent commenced to perform a respiratory function.

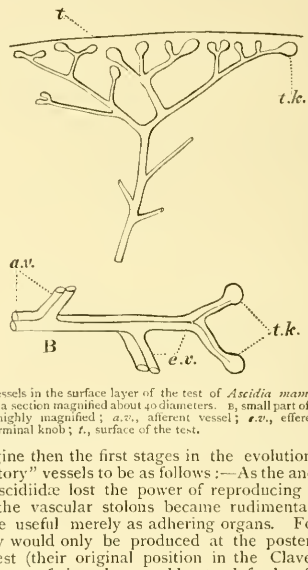

Fig. 5.—Vessels in the surface layer of the test of *Ascidia mammillata* as seen in a section magnified about 40 diameters. B, small part of the system more highly magnified; *a.v.*, afferent vessel; *e.v.*, efferent vessel; *t.k.*, terminal knob; *t.*, surface of the test.

I imagine then the first stages in the evolution of the "respiratory" vessels to be as follows:—As the ancestors[1] of the Ascidiidæ lost the power of reproducing by gemmation, the vascular stolons became rudimentary, until they were useful merely as adhering organs. For some time they would only be produced at the posterior end of the test (their original position in the Clavelinidæ), but in course of time they would extend further forwards along the left side of the body (the side upon which most Simple Ascidians lie) so as to anchor the animal more securely, and we even find them occasionally in this condition in *Ciona intestinalis* and in *Ascidia aspersa* (Fig. 3).

They would then probably (in some not very remote ancestor of *Ciona*) begin, while still acting as adhering organs, to be of some slight use in respiration, and would, consequently, by the action of natural selection, be evolved gradually into a larger system of vessels extending over a wider area of the test. And here might be shown a series of the Ascidiidæ passing from *Ciona* (Fig. 2) through *Corella* (Fig. 4), and *Ascidia plebeia*, in which the system is still very feebly developed and confined to the posterior half of the left side of the

test, by gradual stages to *Ascidia mammillata* (Fig. 5), where the vessels are numerous all over the test, branch freely in its outer layer, and terminate close to the surface in large ovate bulbs, which are usually found filled with blood-corpuscles.

The only part of this history which presents any difficulty is the passage from the Clavelinid to the Cionid arrangement, from the gemmiparous stolon to the first traces of a respiratory system of vessels. This can, I believe, be most satisfactorily explained by assuming that the rudimentary stolons after they had lost their primary function became useful as adhering organs (Figs. 2 and 3), and consequently were retained or possibly increased by the action of natural selection, until their respiratory function became established.

I hope to work out the modifications of the system throughout the various groups of Ascidians in detail, and the results will probably be given in Part II. of the Report on the *Challenger* Tunicata.

W. A. HERDMAN

NOTES

THE Council of the Royal Astronomical Society have awarded their gold medal to Dr. W. Huggins for his researches on the motions of stars in the line of sight and on the photographic spectra of stars and comets. The presentation takes place at the annual meeting next month. This is the second time that Dr. Huggins has received the medal, he having, in 1867, in conjunction with the late Prof. Miller, received it for his researches in astronomical physics.

THE will of Mr. George Bentham, who died in September last, has been proved by Sir Joseph Dalton Hooker and the Right Hon. Sir Nathaniel Lindley, the executors, the value of the personal estate amounting to over 23,000*l*. The testator bequeaths, among other sums, 1000*l*. each to the Linnean Society of London and the Royal Society Scientific Relief Fund. The residue of his real and personal estate is to be held upon trust to apply the same in preparing and publishing botanical works, or in the purchase of books or specimens for the botanical establishment at Kew; or in such other manner as his trustees may consider best for the promotion of botanical science.

AT the meeting of the Colonial Institute on Tuesday, Gen. Sir Henry Lefroy read a paper on the meeting of the British Association in Canada. Sir Lyon Playfair, M.P., referred to the visit of the British Association as marking a point in the advance of civilisation. Canada's position of having federated, not under the pressure of war, but in a time of profound peace, was unique in the history of the world. The science of Great Britain belonged to the Empire, and it was right that Canada should be the first to try to federate the science of the United Kingdom, and distribute it over the Empire. What Canada wanted was not pure science, but applied science, to bind together her vast territory by railways. But knowing that applied science did not come except pure science preceded it, Canada had had the forethought and wisdom to welcome that pure science to the Dominion. Sir Lyon gave a humorous account of an adventure he had in a wild part of Ottawa with a Scotch mining manager. It turned out that the manager, when in Scotland, had attended the Mechanics' Institute at Glasgow, and afterwards the evening classes at the Andersonian Institution, obtaining a knowledge of chemistry and mineralogy, which had stood him in good stead on emigrating to Canada. From his compatriot he (Sir Lyon) heard of many other Scots of a like type, all of whom had got on well, from the scientific education they had acquired at similar institutions. For such men he did not know any better country than Canada to find openings for getting on in the world. Prof. G. T. Bonney spoke at some length of the interesting geological formation of Canada, and said he believed that the district north of the St. Lawrence was rich in valuable minerals, and that exploring parties for their discovery should be organised to supplement the systematic geological survey which was being slowly conducted. He condemned the wasteful treatment of the forests that was going on in some of the parts he had visited, and suggested that it was a matter which should engage the attention of the Dominion Government.

ON Tuesday evening Sir Frederick Bramwell gave an address at the Institution of Civil Engineers on his assuming the chair for the first time since his election as president. Sir Frederick's subject was suggested to him by the forthcoming Exhibition of Inventions, his address consisting mainly of a review of some of the most remarkable recent inventions in the application of science to engineering. Sir Frederick has apparently given up hope of our being able to put the tides to any practical use, and hints that Khartoum might have been relieved long ago had our aeronauts been as inventive, or our War Department as enterprising, as those of France.

M. COCHERY, the French Minister of Posts and Telegraphs, was present, on January 2, at Rouen to witness some interesting experiments in telephoning to a great distance. The object was to test the results of the application between Rouen and Havre, a distance of 90 kilometres, of M. Van Rysselberghe's system of instantaneous transmission. The experiment was perfectly successful, and during more than one hour, messages were exchanged between Rouen and Havre. The Minister announced, on leaving Rouen, that the communication would be open to the public in about a fortnight. Since January 1 the first telephonic offices have been open in Paris, and it is probable that communication will soon be established between Paris and Rouen.

MR. LANT CARPENTER lectures on Sunday at the Sunday Lecture Society, on "The Life and Work of Sir William Siemens," illustrated by experiments, diagrams, and the oxy-hydrogen lanterns. Mr. Carpenter has, we understand, obtained some special materials, of which he will make use in his lecture.

REPORTS from Brussels state that the Spanish earthquake, or a similar simultaneous earthquake, was felt at the Royal Observatory there. The Observatory is stated not to be provided with special instruments for recording earthquakes, as these phenomena are so rare and slight in Belgium. It is said that on December 26 last, the day succeeding the first great shock of the Spanish earthquake, one of the astronomical clocks in the principal meteorological station in the Boulevard de l'Observatoire was stopped, and the other went irregularly. The officer charged with attending to them perceived that the pillars on which they rested had been displaced, and were no longer vertical. On the evening of the same day, M. Lagrange, when about to make some observations, noticed that the large telescope was also displaced. It appears from this that the undulations of the crust of the earth, which have had such disastrous effects in Spain, extended as far as Brussels, and although their effects were not generally appreciable in the latter city, yet they were noticeable in the case of delicate instruments, such as astronomical clocks. It would be interesting to have a precise, authentic statement on this subject, and also to learn whether similar effects were noticed anywhere else in Europe during the last week of the old year.

AT a recent meeting of the German Asiatic Society of Japan a paper was read by Dr. H. Muraoka of Tokio, on the magic mirror of Japan. It is generally supposed that its magical quality was discovered only recently; but it was, says Dr. Muraoka, known for a long time in Japan. Old ladies have

told him that in their youth, fifty years since, they frequently noticed, when at toilet, that the reflection of the sun from the mirror on the wall or ceiling contained the figures or letters on its back. It is said to have been known to the Romans in connection with some of their mirrors, and any one concealing a mirror possessing this quality was arrested as a sorcerer; but the authority for this statement is not given. The subject is engaging considerable attention, as will be seen from the fact that in recent years a list of fourteen writers on the subject is quoted, from Stanislas Julien, in 1847, to Messrs. Ayrton and Perry quite lately; and, as the subsequent discussion showed, there are omissions even in this list. These writers, especially the two latter, have demonstrated beyond doubt that unequal convexities in the mirror beget its magical quality. The polished surfaces are convex, but the convexity is not continuous, and is broken in certain places. After going over what had already been done on the subject, and its results, the author described his own investigations. The riddles of the mirror are far from being all answered by the discovery of unequal convexity. For example, how is the inequality caused—by pressure, heat, or by changes in the molecular tension of the metal plates? The writer tried many experiments to answer the question, and he succeeded by means of chemical agents in drawing lines on the flat back of a mirror, which were reproduced on a reflected image from the front. His results are: That the irregularity in the convexity is caused by the grinding, which alters the molecular tension, that the magic mirror may be produced at will (it was generally supposed to be the work of chance alone), and that the magical quality attributed to it is not confined to Japanese bronze, but is common to all firm, elastic substances. A curious process employed by mirror-workers is described by Dr. Muraoka: it appears to be one of the secrets of the craft. If the surface of a mirror has been made concave by mechanical pressure, the injury is not repaired, as might be expected, by hammering the other side, or otherwise forcing the metal back into its place. The workman takes an iron tool with rounded, but slightly rough, top, and rubs the concave portion of the mirror in all directions, until a fine network of scratches has been formed. The place then rises of itself, and, instead of being concave, becomes more convex than the rest of the surface. This convexity is then shaved away with a knife made for the purpose, until it becomes even with the rest of the mirror. When this is done the whole surface is again ground, polished, and amalgamated.

A STRANGE Japanese custom has, according to the *Japan Mail*, been brought to light by the working of the conscription law. The head of a certain family was instructed that the time had come for his son, whose name was on the census list, to undergo medical examination prior to actual enlistment. The father lost no time in informing the authorities that the individual referred to, though bearing a male name, was his daughter. He explained that having lost two daughters, both about one year old, he had been driven to this expedient to keep the third alive. It appears, further, that in many districts of Japan people still resort, in their anxiety to prolong the lives of their children, to the custom of bestowing upon their offsprings names ordinarily given to infants of the opposite sex, whenever death has made frequent visits to their households. The present case occurred in the capital.

AN important memoir by Lieut. Casey on the North American species of beetles of the sub-family *Stenini* has just been published. It extends to over 200 octavo pages, and describes in minute detail nearly 170 species, of which the greater part are new, and should form one of the most important contributions to systematic entomology in the States that have appeared. "*Stenus*," in the broad sense, is well defined as a whole, but is notoriously difficult in detail. When genera become unwieldy owing to the mass of species included, it is a convenience to students if they can be split up by recognisable divisional characters. Acting on this idea, Casey has split "*Stenus*" into *Stenus* and *Areus*, on tarsal structure. This subdivision equally affects European (and even British) species.

MR. ALDERMAN W. H. BAILEY, as President of the Manchester Society of Engineers, gave an interesting inaugural address on the 10th inst., his subject being "The Reign of Law in Relation to the Unification of Engineering Work." "The reign of law," Mr. Bailey stated, "is imperial in the domain of the engineer. He deals with forces which have definite, fixed values. If he perceives a quantity or a force he knows that he can identify the same measure or quantity of the like whenever he meets with its equivalents under equal conditions. We know that chance does not rule, and if there be conditions that are indefinite or obscure to us it is not because there is no law, but because we are ignorant of its records." This text Mr. Bailey illustrated by reference to the necessity of exact measurement, supporting his position by numerous examples.

PROF. F. ELGAR is about to deliver a special course of evening lectures, in the University of Glasgow, upon "The Buoyancy and Stability of Ships." The course will consist of twelve lectures, commencing on the 22nd inst. These lectures are intended not only for students of this branch of the science of naval architecture, but also for the convenience of draughtsmen and others who are employed in shipyards during the day, and who are unable to attend the regular University classes.

IN the report of the Meteorological Service of Canada for 1884, attention is again called to the advisability of establishing a marine department in connection with the Meteorological Service for the purpose of organising a system of observations on the ocean by steamers crossing the Atlantic and by those trading with ports in Brazil and the West Indies. Canada, having great shipping interests, should, it is thought, take her part in the great international work now going on of charting the meteorological conditions prevalent over the Atlantic, and in the general development of ocean meteorology. Such observations in the North Atlantic would, it is stated, be of great value, especially in perfecting knowledge of the movements of a particular class of storms. Recent investigations on the subject of the climatic relations of Canada to European countries show that the Dominion has the latitudes of Italy, France, Germany, Austria, the British Islands, Russia, Sweden, and Norway, and has as many varieties of climate as have those countries. There is greater cold in winter in many of the latitudes of Canada than in corresponding latitudes in Europe, but the summers are about the same. The most southern part of Canada is on the same parallel as Rome, Corsica, and the northern part of Spain; it is farther south than France, Lombardy, Venice, or Genoa. The northern shores of Lake Huron are in the latitude of Central France, and vast territories not yet surveyed lie south of the parallel of the northern shores of Lake Huron, where the climate is favourable for all the great staples of the temperate zone.

WITH the new year *Cosmos*, the well-known French scientific journal, will enter on a new period. The size will be increased, in order that larger illustrations may be introduced. It will in future consist of 64 columns, two on a page, each of which will contain more matter than its present page.

THE additions to the Zoological Society's Gardens during the past week include a Pig-tailed Monkey (*Macacus nemestrinus* ♂) from Java, a Macaque Monkey (*Macacus cynomolgus* ♀) from India, a Vulpine Phalanger (*Phalangista vulpina* ♀) from Australia, presented by Mr. J. Church Dixon; a Mouflon (*Ovis musimon* ♂) from Corsica, presented by H.R.H. the Duke of Edinburgh, K.G.; a Vulpine Phalanger (*Phalangista vulpina*)

from Australia, presented by Mr. B. C. Parr; a Short-toed Eagle (*Circaëtus gallicus*) from Suez, presented by Capt. H. E. Robbins; a Lacertine Snake (*Cœlopeltis lacertina*) from North Africa, presented by Mr. R. F. Sibbald; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, deposited; a Black and Yellow Hawfinch (*Mycerobus melanoxanthus*) from Yarkland, a —— Pastor (*Sturnia* ——) from the Andaman Islands, four Starred Tortoises (*Testudo stellata*) from India, a Tuberculated Iguana (*Iguana tuberculata*) from South America, purchased.

OUR ASTRONOMICAL COLUMN

The Naval Observatory, Washington.—The Report of the Superintendent of this establishment, Commodore S. R. Franklin, to the Navy Department, for the year ending October 31, 1884, has been issued. Great stress is laid upon the importance of commencing the buildings for the new Observatory. The present site is stated to be notoriously unhealthy, and the buildings are in a dilapidated state, and, as the ground for the new Observatory has been purchased and the plans made and approved, the Superintendent urges that Congress should be appealed to during the coming session for a portion at least of the funds required for the new Observatory. His estimate "For the purpose of erecting a new Naval Observatory and necessary buildings upon the site purchased under the Act of Congress, approved February 4, 1880," amounts to 586,138 dollars, or approximately 120,000*l.* The 26-inch equatorial was chiefly employed in observations of the satellites of Neptune, Uranus, Saturn, and Mars; in the case of Uranus, the observations were confined mostly to the two outer satellites, and have now been discontinued, as the favourable time for determining the position of their orbits has passed. Since this instrument was mounted in 1873 observations of the faint satellites of the planets have constituted its main work, and the laborious discussion of the observations, with the view to the correction of orbital elements, was commenced in earnest in August 1883, and is now in a very advanced state, particularly as regards the satellites of Saturn. A report from Prof. Harkness, in charge of the work for the Transit of Venus Commission, is appended: the measurements of the negatives obtained at the various stations was completed last August; the number of photographic plates giving satisfactory results is 932 for the northern and 639 for the southern hemisphere. Prof. Harkness enters into details with respect to these measures, and the method of conducting them, for which reference must be made to the report. The Superintendent regrets that the printing of the Washington observations is not so advanced as is desirable, and proposes applying to Congress for a sum of 1000*l.* annually for a few years, in order to bring up work to date, after which a smaller sum would allow of the due publication of the observations.

The Dearborn Observatory, Chicago.—The report of the Director of this Observatory, Prof. G. W. Hough, dated June 18, 1884, has been received within the past week. The work with the 18-inch equatorial was confined, as usual, during the previous year to the observations of a few special objects, including Pons's comet of 1812 on its reappearance, difficult double-stars, the planet Jupiter, and the satellites of Uranus. Thirty-two new double-stars, most of which are difficult, were detected. The companion of Sirius was measured by Prof. Hough on eleven nights, and by Mr. Burnham on ten nights, the mean result being

1884·185 ... Position, 36°·6; Distance, 8″·45.

which, with the observations of recent years, seems to indicate that the period of revolution of the companion is longer than that indicated by theory. The disk of Jupiter was observed on every favourable occasion, and micrometric measures made on the principal spots and markings, including the great red spot first remarked in 1878. With best vision the colour of this object in 1883-84 was "unmistakably a pale pink." The spot is stated to have maintained its size, shape, and outline during the five years it has been observed at Chicago; in this respect experience there has not fully accorded with the impressions of some observers, that the spot had "lost its outline, and become merged in a faint belt on the following end." The most marked change has been in its degree of visibility, but it was seen at Chicago as long as the planet was observable. Prof. Hough adds that from 1879 to 1883 the spot had a retrograde drift in longitude upon the surface, or, in other words, the apparent rotation of Jupiter was increased from 9h. 55m. 34·0s. in 1879 to 9h. 55m. 38·4s. in 1883. During the last opposition this drift appears to have nearly ceased. The mean period from September 12, 1883, to June 11, 1884, comprising 660 rotations, is 9h. 55m. 38·5s., and the mean for the whole five years of observation is 9h. 55m. 37·0s. The report is accompanied by six tinted lithographs of the appearance of Jupiter's disk. Saturn was frequently examined with the view to detecting markings on the rings, but all observations so far in this direction have been negative. While the rings have been sharply defined, and even the boundary of the dark ring well seen, "nothing indicating a division in the outer ring has ever been noticed." This is not in accord with the conclusion of many other observers provided with telescopes of less optical capacity than the Dearborn refractor.

GEOGRAPHICAL NOTES

A so-called "envoy" of the Mayor of Timbuktu, lately arrived in Paris, has been received by the French President, and introduced to the Geographical Society at its last meeting. On this occasion it was stated that there is no Sultan or military authority in this famous metropolis of Negroland, but only a body of merchants who yearly elect a kind of mayor from amongst themselves. This statement is not quite correct, and, as little is known regarding the internal affairs of the city, the following facts will be acceptable:—For over 200 years Timbuktu has been administered by a "Kahia," a kind of burgomaster, originally appointed by the Emperor of Marocco from the Moorish Andalusian family of Er-Rami some time after the expulsion of the Arabs from Spain. The office became hereditary in this family, and the present Kahia, or "Amir," as he now affects to call himself, is Muhammed Er-Rami, whose Negroid features are the result of long alliances with the surrounding Souhray population. He commands little influence, and is practically a mere puppet in the hands of whichever of the rival Arab, Imosharh (Berber) or Fulani (Fulah), factions happens for the time being to have the upper hand. The Imosharhs command the whole district between Timbuktu and Arawán, and their Sheikh or "Sultan," Eg-Tandagumu, seems to draw his chief supplies from the plundered caravans passing through his territory. The Arabs, as in the time of Barth, are still ruled by the head of the illustrious El-Bekay family, a branch of the Kuntza tribe, whose present chief is Sheikh Abadin. His policy has long been to side with the Fulani, whose power here, as elsewhere in the Western Sudán, is constantly on the increase, and who threaten to become absolute masters of Timbuktu unless this place falls into the hands of some European power advancing from the west or penetrating up the Niger valley from the south.

According to the *Turkestan Gazette*, Dr. Grishimailo, the traveller and entomologist, has concluded his investigations into the natural history of Turkestan for the present. He began his travels in the Fergana Valley, and from thence he went into the Altai region, which he examined thoroughly. In the course of the summer he visited Osch, Arawan, Nankat, Utch-Kurgan, Shahimardan, Karakazyk, Koksu, Tekelik, the River Balykty, Karamuk, and Zanku; on his return he visited Karamuk, Jirgetal, Sarzbulak, Koksu, Altyumazar, and went on foot through the Trans-Altai Mountains to Bordooba and Karakul. The geological collections are very considerable. In lepidoptera alone there are 17,000 specimens, amongst them being many new kinds. The expedition was also a success from an ethnographical and anthropological point of view. Many heights were measured and thermometrical observations made throughout the whole journey. The traveller met many evidences of the existence of a glacial epoch in Central Asia: amongst these are mentioned the presence of forms in Thian-shan, which hitherto have only been found in Labrador, Greenland, Lapland, and the Swiss Alps. Next year Dr. Grishimailo contemplates visiting the western offshoots of the Thian-shan range, because this locality has never yet been examined thoroughly from a geological point of view.

At the last meeting of the Geographical Society of St. Petersburg, M. Beliaffsky made a communication respecting the journey which he undertook in order to explore the central road

leading to the interior of Central Asia. This road is much shorter than the usual route, but was considered until very lately as the worst and most difficult. But upon examining the obstacles presented by the road, and principally the alleged impossibility of effecting a passage through Mertvy, Koultouk, Oust-Oust, &c., M. Beliaffsky found the assertion to be erroneous, and therefore pronounces himself in favour of the road he has explored. In order to render it still more easy, he proposes that regular communication should be established on the Caspian Sea between Astrakhan and Cesarewitch Bay, that two lighthouses, at least, should be constructed; that a steam navigation service should be established on the Amu-Doria, and a road practicable for vehicles made through the sands between the Amu-Doria and Khiva.

THE last (xi.) of Mr. Lansdell's series of interesting letters from Central Asia in the *Times*, describes his journey by boat down the Oxus, from Charjui to Khiva. In referring to the fish of the Oxus, he mentions the *Scaphyrincus*, a kind of sturgeon, the discovery of which in Central Asia, a few years ago, made quite a flutter among the students of ichthyology by reason of its resemblance to one of the North American sturgeons, which was found for a long time in the Mississippi only, until Fedchenko discovered one in the Syr Daria, and subsequently M. Bogdanovitch found another species in the Lower Oxus. The Oxus fish is known as *Scaphyrincus kaufmanni*. M. Bogdanovitch points out its interest from a geological point of view. "In the Palæozoic period," he says, "the ganoid fishes used to inhabit all the waters of the world in a great number of forms, comprising almost entirely the ichthyological fauna of that period. At the period of the Devonian formation this group of fishes seems to have reached its highest development, and in the strata of this formation are preserved the most numerous remains of its representatives. In the succeeding geological period this group appears to fall and die out, giving place to a group of *Teleostei* or bony fishes, which inhabited at that time all the waters of the world in a number of forms."

ON December 3, 1884, was celebrated, in the Scandinavian kingdoms, the bi-centenary of the birth of Ludwig Holberg, "the northern Molière" Prof. Erslev took advantage of the occasion to bring to the notice of the Danish Geographical Society the services to geography of the great dramatic poet in his generation. When Holberg was appointed Professor of History and Geography in 1730, the latter science was in a bad plight everywhere, and especially in Denmark. According to the curriculum, the Professor had to hold a reading once a fortnight on geography, but it is not known whether these readings actually took place. Holberg's great interest in geography is evident, not only from his own geographical writings, but also from many of his observations elsewhere. He betook himself with much eagerness to the study of the subject; in a preface to Van Howen's "Journey to Russia" (1743) he recommended others to write similar descriptions of their journeys. His own first geographical work was a description of Denmark and Norway (1729), the second "An Account of the Celebrated Norwegian Commercial City, Bergen" (1737), which is said to be useful even still. His third work was a geographical textbook in Latin, entitled "Ludovici Holbergii Compendium Geographicum in usum Sudiosi Juventulis," of which there were several editions both in Copenhagen and Leipzig. The work was translated into English in 1758, with a small universal history by Holberg. Some editions of it belong now to the class of bibliographical rarities. His work was edited after his death by Pastor Jonge, but Holberg's fifty-eight small obtavo pages grew into seven large quarto volumes.

CAPT. WILLARD GLAZIER, of the United States Navy, has communicated to the English Royal Geographical Society his discovery of the true source of the Mississippi. This has long been a vexed question, and in June, 1881. Capt. Glazier organised and led an expedition with the object of finally settling the matter. The expedition proceeded in canoes *viâ* Leech Lake to Lake Itasca, and, accompanied by an old Indian guide, pushed forward to the south; and the captain was rewarded by the discovery of another lake of considerable size, which proved to be, without the shadow of a doubt, the true source of the Mississippi. It is in lat. 47° 13′ 25″, and the lake is 3 feet above Lake Itasca, the hitherto supposed source of the river. The Mississippi may, therefore, be said to originate in an altitude 1578 feet above the Atlantic Ocean, and its length, taking former *data* as the basis, may be placed at 3184 miles. The tract of country in which the river originates is a remote and unfrequented region.

AN embassy of two hundred and fifty representatives of the aboriginal tribes of Western China, which recently arrived at Pekin, has led a writer in the *North China Herald* to give some information with regard to these little-known peoples. These tribute-bearers are under the charge of native chiefs, who are responsible to the Chinese authorities of the province for the maintenance of order, and the fulfilment of all recognised obligations, one of which is that of visiting Pekin once in twelve years with tribute. The localities from which they come are scattered over the country from Yennan to Kan-su, all along the Thibetan border of Sze-Chuan. At one time their name, Tu Sze, or "aboriginal officers," embraced all the aboriginal tribes in Western and South-Western China. The Chinese never had the aid of ethnology to guide them in discriminating between subject peoples by their languages, customs, physical characteristics, and religious beliefs, but they have collected the materials for judging, and we now know, generally speaking, in what category to place the different races met by travellers in Western China. The Lolos of Sze-Chuan are allied to the Burmese, the tribes represented at Pekin, who are also called Hsi Fans, are Thibetans. Both may be called the Mon-Bod family, or Western Himalaic, according as the ethnological inquirer prefers to determine his nomenclature by mountain chains, or by the most prominent race-names prevailing among the people themselves. The Thibetans and Hsi Fans prefer Bod for their race-name, as the Burmese do Mon. The rest of the aboriginal tribes in Western China and in the southern provinces, whether Miao, Yao, or Tung, seem all to belong to the Eastern Himalaic branch, or that of the Siamese, the Laos tribes, the Shan tribes of the Indo-Chinese peninsula, the Li tribes of Hainan, and the Cambodians and Cochin Chinese. The Lolos, as described by M. Baber, live in their own mountains apart, and seem to be a nation, while the Hsi Fans live in scattered tribes whose natural home is Thibet. They are short of stature, fond of red clothing, and, as to shape, adopt Chinese fashions in no small degree. Their faces are rounder than the Chinese, their heads smaller, their noses less stunted, and, while small, stand out to a point. Their eyes are small, placed in a line, and have a bright black lustre. They are a quiet race now; but history shows that they struggled bravely against the all-conquering Chinese. Details respecting the twelve Hsi Fan tribes of Sze-Chuan are to be found in numerous Chinese books, and there are also many official and private accounts of the wars which ended in their subjection.

DR. DOMENICO LOVISATO'S paper on Tierra del Fuego, reprinted from a recent number of Guido Cora's *Cosmos*, adds considerably to our knowledge of that inhospitable region and its inhabitants. The division of the latter into three distinct groups, Ona in the east, Alaculuf in the west, and Yahgan in the south, is fully confirmed. But the two latter appear to be fundamentally one, constituting a single type of "Asiatic" descent, while the first mentioned is certainly of Tehuelch (Patagonian) stock. The Onas, all hunters, number about 20 0; the Yahgans, mainly fishers, perhaps 3000; the Alaculufs, hunters and fishers, 3000; giving a total population of not more than 8000 to the whole archipelago. All seem to present more or less indications of degeneracy from a higher state of culture, due probably to long isolation in this unfavourable environment since its separation in early quaternary times from the mainland. That it was inhabited by the ancestors of the Yahgans and Alaculufs even before the opening of Magellan Strait, appears evident, especially from the numerous kitchen-middens, some of vast size and great antiquity, scattered over the archipelago. Those of Elizabeth Island, by far the largest, the oldest, and in every respect the most interesting, run in one direction a distance of nearly a mile to a deep barranca, or ravine, beyond which they again stretch away for an interminable length along the coast. They stand at an elevation of from twenty to twenty-five feet above the present sea-level, and consist of a lower stratum of shells, bones, and other refuse, succeeded by a layer of fine sea-sand forty-five to fifty inches thick, above which comes an accumulation of rich vegetable humus overgrown with an abundant herbaceous vegetation. Whether the layer of sea-sand has been washed up or was deposited during a temporary subsidence of the land cannot be determined without further research. But in either case its presence bespeaks a vast antiquity for the lower stratum of refuse, which has an average depth of over three feet, and which contains the shells of *Mytilus pata*

gonicus, of *Aulacomya magellanica*, of *Patella magellanica*, fragments of *Otaria jubati*, and a few other mammals, but no human remains, no traces of pottery, no bones split for the extraction of the marrow, no arms or manufactured objects beyond a few rude spear- or arrow-heads. All this offers the most striking analogy to the more recent and modern refuse heaps now being formed, and seems to point at a continuity of population since early quaternary times. The absence of human remains or split bones might even imply that the primitive inhabitants, like their present descendants, were at no period addicted to anthropophagy. In other respects the latter occupy an extremely low social position. They practise no arts beyond the manufacture of frail bark canoes, unchanged since the time of Drake's visit, shell knives, bows, darts, and harpoons. The wigwams are branches stuck in the ground and gathered to a point above, or else a mere guanaco skin (among the Onas) suspended from a tree to windward. Their food is mainly fish, crustaceans, wild berries, mushrooms, cetaceans, greedily devoured in a highly putrescent state. They believe in ghosts and demons, but have no idea of a god, or of any religious worship; are guided rather by instincts than by reason; lack even the maternal sentiment, at least after the period of weaning; show no feeling of real affection for friends or kindred, the only developed sentiment being that of pure selfishness. Their stupidity is such that they are unable to count beyond three, after which everything is *vuru*—much, many. Yet, in the face of all this the writer was assured by the English missionaries now evangelising these primitive or debased peoples, that the language of the Yahgans, into which they have translated the Gospel of St. Luke, contains no less than 30,000 words, "a wealth contrasting strangely with their present low state of culture, and naturally suggesting the hypothesis of an origin very different and far superior to the present." But, assuming a former higher state, the difficulty is to understand how such a rich linguistic inheritance could have been preserved for countless generations in their present degraded condition, and amid the adverse surroundings of their present habitat. On this subject clearly more light is demanded.

CHARACTERISTICS OF THE NORTH AMERICAN FLORA[1]

II.

THIS contrast is susceptible of explanation. I have ventured to regard the two antipodal floras thus compared as the favoured heirs of the ante-Glacial high northern flora, or rather as the heirs who have retained most of their inheritance. For, inasmuch as the present Arctic flora is essentially the same round the world, and the Tertiary fossil plants entombed in the strata beneath are also largely identical in all the longitudes, we may well infer that the ancestors of the present northern temperate plants were as widely distributed throughout their northern home. In their enforced migration southward, geographical configuration and climatic differences would begin to operate Perhaps the way into Europe was less open than into the lower latitudes of America and Eastern Asia, although there is reason to think that Greenland was joined to Scandinavia. However that be, we know that Europe was fairly well furnished with many of the vegetable types that are now absent, possibly with most of them. Those that have been recognised are mainly trees and shrubs, which somehow take most readily to fossilisation, but the herbaceous vegetation probably accompanied the arboreal. At any rate, Europe then possessed Torreyas and Gingkos, Taxodium and Glyptostrobus, Libocedrus, Pines of our five-leaved type, as well as the analogues of other American forms, several species of Juglans answering to the American forms, and the now peculiarly American genus Carya, Oaks of the American types, Myricas of the two American types, one or two Planer-trees, species of Populus answering to our Cotton-woods and our Balsam-poplar, a Sassafras, and the analogues of our Persea and Benzoin, a Catalpa, Magnolias, and a Liriodendron, Maples answering to ours, and also a Negundo, and such peculiarly American Leguminous genera as the Locust, Honey Locust, and Gymnocladus. To understand how Europe came to lose these elements of her flora, and Atlantic North America to retain them, we must recall the poverty of Europe in native forest trees, to which I have already alluded. A few years ago, in an article on this subject, I drew up a sketch of the relative richness of Europe, Atlantic North America, Pacific North America, and the eastern side of temperate Asia in genera and species of forest trees (*Am. Journ. Sci.* iii. vi. 85). In that sketch, as I am now convinced, the European forest elements were somewhat under-rated. I allowed only 33 genera and 85 species, while to our Atlantic American forest were assigned 66 genera and 155 species. I find from Nyman's Conspectus that there are trees on the southern and eastern borders of Europe which I had omitted, that there are good species which I had reckoned as synonyms, and some that may rise to arboreal height which I had counted as shrubs. But on the other hand and for the present purpose it may be rejoined that the list contained several trees, of as many genera, which were probably carried from Asia into Europe by the hand of man. On Nyman's authority I may put into this category *Cercis Siliquastrum*, *Ceratonia Siliqua*, *Diospyros Lotus*, *Styrax officinalis*, the Olive, and even the Walnut, the Chestnut, and the Cypress. However this may be, it seems clear that the native forest flora of Europe is exceptionally poor, and that it has lost many species and types which once belonged to it. We must suppose that the herbaceous flora has suffered in the same way. I have endeavoured to show how this has naturally come about. I cannot state it more concisely than in the terms which I used six years ago.

"I conceive that three things have conspired to this loss of American, or as we might say, of normal types sustained by Europe. First, Europe, extending but little south of lat. 40°, is all within the limits of severe glacial action. Second, its mountains trend east and west, from the Pyrenees to the Carpathians and the Caucasus beyond; they had glaciers of their own, which must have begun their work and poured down the northward flanks while the plains were still covered with forest on the retreat from the great ice forces coming from the north. Attacked both on front and rear, much of the forest must have perished then and there.

"Third, across the line of retreat of whatever trees may have flanked the mountain ranges, or were stationed south of them, stretched the Mediterranean, an impassable barrier. . . . Escape by the east, and rehabilitation from that quarter until a very late period, was apparently prevented by the prolongation of the Mediterranean to the Caspian, and probably thence to the Siberian Ocean. If we accept the supposition of Nordenskjöld that, anterior to the Glacial period, Europe was 'bounded on the south by an ocean extending from the Atlantic over the present deserts of Sahara and Central Asia to the Pacific,' all chance of these American types having escaped from and re-entered Europe from the south and east seems excluded. Europe may thus be conceived to have been for a time somewhat in the condition in which Greenland is now. . . . Greenland may be referred to as a country which, having undergone extreme glaciation, bears the marks of it in the extreme poverty of its flora, and in the absence of the plants to which its southern portion, extending six degrees below the Arctic circle, might be entitled. It ought to have trees and it might support them. But since their destruction by glaciation no way has been open for their return. Europe fared much better, but has suffered in its degree in a similar way" (*American Journal of Science*, *l.c.*, p. 194).

Turning to this country for a contrast, we find the continent on the eastern side unbroken and open from the Arctic circle to the tropic, and the mountains running north and south. The vegetation when pressed on the north by on-coming refrigeration had only to move its southern border southward to enjoy its normal climate over a favourable region of great extent; and, upon the recession of glaciation to the present limit, or in the oscillations which intervened, there was no physical impediment to the adjustment. Then, too, the more southern latitude of this country gave great advantage over Europe. The line of terminal moraines, which marks the limit of glaciation, rarely passes the parallel of 40° or 39°. Nor have any violent changes occurred here, as they have on the Pacific side of the continent, within the period under question. So, while Europe was suffering hardship, the lines of our Atlantic American flora were cast in pleasant places, and the goodly heritage remains essentially unimpaired.

The transverse direction and the massiveness of the mountains of Europe, while they have in part determined the comparative poverty of its forest vegetation, have preserved there a rich and widely distributed Alpine flora. That of Atlantic North America

[1] An Address to the Botanists of the British Association for the Advancement of Science; read at Montreal to the Biological Section, August 29, 1884, by Prof Asa Gray. Continued from p. 235.
